The experimental protocols adopted by neuroimaging and electrophysiology studies to assess residual brain function in patients with disorders of consciousnesses include data acquisitions both in resting state conditions and after external stimulation. With appropriate experimental design, these technologies also permit detection of nonverbal command-following and may even establish methods of communication with some behaviorally unresponsive patients.

Resting State Passive Paradigms

In resting conditions, when we do not perform any task and receive no external stimulation, our brains are not inactive. It rather seems that in the resting state, there is some kind of typical cognitive activity when the mind is unconstrained and wanders (e.g., Mason et al. 2007; Raichle and Snyder 2007). We have recently characterized the phenomenological complexity of such cognitive process by two components: *external* awareness, namely, everything we perceive through our senses (what we see, hear, feel, smell and taste), and *internal* awareness or stimulus-independent thoughts (Demertzi et al. 2013c). In a combined behavioral-neuroimaging experimental setup (Vanhaudenhuyse et al. 2011), we first showed that external and internal awareness behavioral ratings were anticorrelated and that there was a switch in their dominance at a similar frequency as observed in the fMRI BOLD signal (Fransson 2005). Interestingly, the switch between the external and internal milieu was found not only to characterize overt behavioral reports but also had a cerebral correlate, More particularly, it was shown that behavioral reports of internal awareness were linked to the activity of midline anterior cingulate/mesiofrontal areas as well as posterior cingulate/precuneal cortices. Inversely, subjective ratings for external awareness correlated with the activity of lateral fronto-parieto-temporal regions. Such fMRI resting state studies show that a network of brain areas seems to play an important role in sustaining consciousness. Functional connectivity in the posterior cingulate cortex, medial prefrontal cortex, and posterior parietal cortices (these areas broadly known as the default mode network-DMN) show no functional connectivity in brain death (Boly et al. 2009; Soddu et al. 2011). Additionally, the functional connectivity pattern of this network was found to decrease as a function of the level of consciousness, ranging from controls and patients with locked-in syndrome to MCS, VS/UWS, and coma (Vanhaudenhuyse et al. 2010). More recently it was shown that more networks during resting state (Heine et al. 2012) show disrupted connectivity in patients,

which was able to discriminate them from healthy subjects with 85& accuracy (Demertzi et al. in press). Although the value of the fMRI resting state as a differential diagnostic tool remains to be determined, the potentially prognostic value of DMN connectivity was shown in a cohort of patients in the acute stage of coma for whom the presence of DMN functional connectivity was correlated with reversibility of coma. That is, preserved functional connectivity of the DMN was observed in those patients who subsequently regained consciousness and was disrupted in all patients who failed to recover their consciousness levels, suggesting that resting state DMN connectivity may serve as an indicator of the extent of cortical disruption (Norton et al. 2012).

PET studies in resting state show that unresponsive patients compared to healthy subjects are characterized by reduced levels of global metabolism. Interestingly, recovery from VS/UWS does not necessarily coincide with resumption of global metabolic activity (Laureys et al. 2004a). Rather, some areas appear to be more important than others for conscious function. For instance, patients in VS/UWS show impaired metabolism in a widespread network encompassing midline (i.e., anterior cingulate/mesiofrontal and posterior cingulate cortex/precuneus) and lateral (i.e., prefrontal and posterior parietal) associative cortices, compared to healthy controls (Laureys et al. 1999). Importantly, functional connections of these areas with the thalami were restored after recovery from VS/UWS (Laureys et al. 2000). Using PET, it was recently shown that VS/UWS patients compared to healthy controls exhibit metabolic dysfunction in both external and internal awareness networks as well as in the thalami. In contrast, MCS patients compared to healthy controls showed dysfunction mostly in internal awareness network and thalami, which could reflect an altered self-awareness in these patients that is difficult to quantify at the bedside (Thibaut et al. 2012).

Various EEG paradigms have also made an effort to differentiate between the clinical entities of disorders of consciousness. Fifteen-minute EEG resting state acquisitions showed that VS/UWS patients had significantly higher correlated oscillations than MCS in the delta frequency band (Lehembre et al. 2012). Such delta frequency activity is represented as a high amplitude brain wave with a oscillation between 0 Hz and 4 Hz usually associated with the deepest stages of sleep also known as slow-wave sleep (SWS). As previously shown, power in the delta band also increases with severity of disorders of consciousness (Leon-Carrion et al. 2008). Similarly, the bi-spectral index, a measure of the depth of anesthesia, was shown to discriminate between VS/UWS and MCS patients (Schnakers et al. 2005). The bi-spectral index was also positively correlated with behavioral scores of awareness at the time of testing and associated with outcome results at 1 year post-trauma. Additionally, an EEG entropy score of 52 (value ranging from 0 to 91, with higher scores indicating higher consciousness level) was shown to be able to differentiate acutely unconscious from MCS patients with 89 % sensitivity and 90 % specificity. However, the prognostic value of this measure was not high. At 1-year follow-up in the acute setting, patients with good outcome (i.e., recovery of functional communication) could be discriminated from those with bad outcomes (death or still in VS/UWS) with a specificity of 78 % and sensitivity of 60 % at the

entropy value of 57. Considering the moderate discrimination capacity of entropy measures for outcome this clinical feature cannot be recommended as a prognostic tool (Gosseries et al. 2011). Other efforts have also been made to use EEG signal patterns as a prognostic tool for these patients. For example, it has been observed that VS/UWS patients who made a behavioral recovery at the 3-month follow-up showed higher occipital source power in the alpha band of resting EEG when compared to those who did not (Babiloni et al. 2009). Normally, high power of pre-stimulus cortical alpha rhythms (about 8–12 Hz) underlies conscious perception in healthy subjects. As such, cortical sources of resting alpha rhythms might predict recovery in VS/UWS patients.

Taken together, resting state studies with fMRI, PET, and EEG provide promising techniques for assessing residual brain function in patients with disorders of consciousness, thanks to their simple and fast application and the fact that no collaboration is needed on patients' behalf. It should be noted, however, that in terms of differential diagnosis, no A-level recommendations can be made yet favoring a particular type of testing. Large multicentric studies are necessary to validate their diagnostic power and determine their prognostic value.

Activation Studies

Importantly, brain responses to external stimuli provide valuable information not only about the preserved functional (and to some degree anatomical) connectivity among distinct brain regions but also about the nature of detected responses. The potential for pain perception in MCS patients is suggested by findings of cerebral correlates of pain processing in a network similar to that in healthy controls (Boly et al. 2008). The activation pattern observed in MCS patients was also much more widespread than in VS/UWS patients, suggesting a difference in capacity for pain perception. The type of stimuli used also seems to make a difference to the observed neural responses and therefore further assists in the inference of awareness. Stimuli with emotional valence, such as infant cries and the patient's own name, induced a much more widespread activation in MCS patients than did meaningless noise (Laureys et al. 2004b). The activation pattern was comparable with that previously obtained in healthy controls. Patients also showed higher fMRI activity in the anterior cingulate cortex after listening to their own name as compared to listening to a familiar name, and this activity correlated with the behaviorally assessed level of consciousness of the patient (Qin et al. 2010). Such results imply that self-referential stimuli, like one's own name, are attention grabbing and therefore can be used in the assessment of residual brain function of these patients.

EEG studies measuring effective connectivity also seem to be able to differentiate between VS/UWS and MCS patients. Effective connectivity is a measure of the causal relationship between brain areas. One study using a mismatch negativity paradigm and applying dynamic causal modeling found that the only significant difference in functional connectivity between VS/UWS and MCS patients was an impairment of backward connectivity from frontal to temporal cortices (Boly et al. 2011).

Also, measurement of EEG effective connectivity after the application of transcranial magnetic stimulation (TMS) revealed that VS/UWS patients showed a simple, local response after the TMS pulses. In contrast, MCS patients showed more complex activations after the TMS pulses which involved distant cortical areas ipsilateral and contralateral to the site of stimulation (Rosanova et al. 2012). A number of studies have used event-related potentials (ERPs: averages of segments of EEG locked to the presentation of a stimulus) to assess patients with disordered consciousness. In healthy subjects, even though early "exogenous" components (elicited within 100 ms after stimulus presentation) are known to persist even in unconsciousness, later "endogenous" ERP components (e.g. P300, i.e., showing a positive peak 300 ms after stimulus presentation) can be used to infer conscious cognitive processing of information (Vanhaudenhuyse et al. 2008a). In several ERP studies, the detection of the patients' own name was used in order to assess residual linguistic preservation and self-processing. When their own name was presented infrequently among other names, a differential P300 has been observed in locked-in syndrome, MCS and VS/UWS patients, implying that the auditory system was relatively preserved in response to language stimulation (Schnakers et al. 2008, 2009a). This suggests high-level cognitive processing for auditory stimuli beyond their most basic features in patients with disorders of consciousness.

Active Paradigms

The primary challenge with many activation studies is that, in the absence of a subjective contribution from patients, a similar-to-control brain activation pattern cannot necessarily be interpreted as evidence of a conscious percept. In that respect, paradigms measuring command-following by means of mental imagery appear more promising for allowing inferences of awareness in behaviorally unresponsive patients. The first of such "active" mental imagery paradigms was developed using fMRI. Healthy volunteers were asked to perform a series of mental tasks (e.g., imagine singing a song in your head or imagine your mother's face). The most robust and distinguishable patterns of brain activation were obtained using motor mental imagery (i.e., imagine playing tennis) and spatial navigation (i.e., imaging walking around in your house). These two distinct tasks led to the predicted activation of supplementary motor cortex and parahippocampal areas, respectively (Boly et al. 2007). Initially, the use of this paradigm in a clinically diagnosed VS/UWS patient showed brain activation to both mental tasks indistinguishable from controls, suggesting preserved awareness in this patient preceding clinical evaluation (Owen et al. 2006). In a larger cohort of 54 patients clinically diagnosed as being either VS/UWS or MCS, five patients showed robust fMRI evidence of response to these two mental task commands (Monti et al. 2010). The best explanation for their ability to exhibit brain activity differentially responding to verbal commands is that they were consciously aware of, understood, and could comply with the instructions. In one patient, functional communication was established by explaining to the patient to do the motor imagery task to communicate "yes" and the spatial navigation task to

communicate "no." The automated user-independent analysis of the acquired fMRI data classified the brain's responses as a "yes" or "no" answer to a series of simple questions. Correct answers were obtained and reported by blinded examiners for five consecutive questions. Only for the final question could no determinate answer be elicited, due to absent brain activation. This patient was originally diagnosed as VS/UWS on the basis of standardized behavioral assessments, but the fMRI results showed that he was actually in an MCS (Monti et al. 2010). Thus, the fMRI experiment can identify instances of clinical misdiagnosis, which are probably frequent in clinical settings (Schnakers et al. 2009b). This patient could also be considered to be in a functional LIS, given that it was only functional neuroimaging that permitted the establishment of the yes-no communication to closed questions (Bruno et al. 2011b).

Unfortunately, such "active" paradigms currently can only be seen as a proof of concept rather than a practical communication tool. As soon as the patient was removed from the MRI machine, no further communication was possible. Hence, portable and cheaper EEG-based equivalents (e.g., Cruse et al. 2011, 2012; Lule et al. 2013) are being developed for more routine clinical use (for recent review see Chatelle et al. 2012). Such brain-computer interfaces (BCIs) have already been used successfully in clinical settings.

It is important to stress that the absence of brain activation to commands cannot be taken as proof of absence of consciousness. Repeated fMRI and EEG BCI assessments are needed to increase the confidence for true negative findings. There is also the problem of false-positives, namely, the fact that unconscious patients may show artifact or noise-related activation (Soddu et al. 2011). Future studies should deal with these issues in large patient cohorts and should also assess test-retest variability of these novel technologies in this specific context. What remains to be shown, however, is whether such technologies can be used as evidence of the expressed will of a competent patient (Gantner et al. 2012). For example, how can a negative response of an "unresponsive" patient to the question of whether they want to continue to live be considered as a reliable response to be respected? Similarly, should pain treatment in an MCS patient change once they communicate that they suffer? Should proving consciousness in these patients be considered as piece of evidence to be celebrated, or can it work against patients' and families' best interests? (Jox et al. 2012) These aforementioned questions require answers that future establishment of ethical and legal provisions can provide.

Conclusions and Future Directions

Using advanced neuroimaging and electrophysiology techniques, a number of clinically unresponsive patients may show remnants of preserved awareness, judging from their ability to follow commands and in some cases even communicate through their willfully modified brain activity. Studies of this kind highlight the pitfalls of forming a diagnosis based on behavioral assessments only. Using these techniques, the gray zones between the different disorders of consciousness in the

clinical spectrum following coma are beginning to be better defined (Laureys and Boly 2008). It should be stressed that these exciting developments are not yet routine in clinical practice. The first obstacle that needs to be overcome before the methodologies discussed above can enter clinical practice relates to ethical concerns. For example, in terms of treatment planning, such as pain management and end-of-life decision making, patients with disorders of consciousness are now offered the possibility to express their preferences by means of brain-computer interfaces. What remains to be clarified is the degree to which such indirect responses can be considered reliable and worthy of legal representation. It is expected that these methods will eventually help clinicians and other caregivers understand the state of disordered consciousness of their patients.

Abstract

Neuroimaging techniques can generate a variety of kinds of personal information. This chapter focuses on the potential for neuroimaging to threaten privacy by revealing mental content and discusses the scientific and ethical issues that should be considered in a neuroethical analysis of neuroimaging that may infringe on privacy. Here these considerations are illustrated with a discussion of the scientific and ethical issues that arise when trying to use neuroimaging technologies for lie detection in real-world applications. Although current methods do not significantly threaten mental privacy, it is possible that privacy rights could be infringed with further developments in neuroimaging. However, this area is highly undertheorized; more work on the foundations of the right to privacy is needed.

Introduction

Neuroimaging techniques have the potential to generate personal information of various sorts. Already they can provide clinicians with important information about an individual's health. For example, brain scans have already been shown to be useful for diagnosing current and predicting future disease states, such as dementia (Teipel et al. 2013), and they are becoming increasingly diagnostic for certain kinds of psychiatric disorders (de Oliveira-Souza et al. 2008; Du et al. 2012; Greicius 2008; Rametti et al. 2011). In addition, scanning healthy subjects for cognitive research studies occasionally results in incidental findings with medical implications, such as the presence of a brain tumor or aneurism (Illes et al. 2006; Scott et al. 2012). Personal information regarding health could be useful to a variety of parties, such as insurance companies and employers. It goes without saying that the interests of some parties may not align with those of the subject, and thus the question of privacy arises.

The potential uses of neuroimaging information extend far beyond the medical realm. Neuroimaging can also generate a wealth of information about a person's behavior, proclivities, and experiences. In some cases, this kind of information can be obtained in seemingly neutral tasks and thus could be obtained without the subject's consent. There is evidence, for example, that neuroimaging can allow inferences about certain character traits (Blackford et al. 2011; Carre et al. 2013; Laricchiuta et al. 2013; Lemogne et al. 2011; Van Schuerbeek et al. 2011); relevance to employment decisions and law enforcement is obvious. The potential to predict future dangerousness or recidivism with the help of brain data is clearly relevant to the legal system and to law enforcement (Aharoni et al. 2013; Clark et al. 2014; Nadelhoffer et al. 2010). As we get more data and develop more sophisticated classifiers, the predictive power of neuroimaging is bound to increase. Mounting evidence suggests that some standard paradigms provide information about implicit attitudes and biases, such as racial or gender biases (Azevedo et al. 2012; Bruneau and Saxe 2010; Knutson et al. 2007; Krill and Platek 2009; Van Bavel et al. 2008). The obvious application of neuroimaging technology to lie detection could have significant influence in legal proceedings, in employment, and in other types of social settings as well (Hakun et al. 2009; Kozel et al. 2005; McCabe et al. 2011; Monteleone et al. 2009; Schauer 2010; Spence 2008; Wolpe et al. 2005). Finally, some recent studies have demonstrated the ability of fMRI to discern certain aspects of mental content, raising the specter that imaging can read minds (Chang et al. 2011; Haynes 2009; Mitchell et al. 2008; Nishimoto et al. 2011; Shinkareva et al. 2011; Soon et al. 2008).

While the science behind this is fascinating, the results may be disturbing. The growing ability of neuroimaging to produce information about mental content has led to the worry that neuroimaging threatens a boundary that has been inviolate since the dawn of humanity: the privacy of the contents of one's own mind. We are accustomed to thinking that the contents of a person's mind are directly accessible only to himself; indirect access may be granted to others through voluntary acts, such as speech, gestures, or actions. While this stark picture is not strictly true, as involuntary signals such as facial expressions can also provide a window into the contents of a person's mind, it is close enough to true that the

prospect of accessing mental content through technology could be a game changer. The ability to obtain information about mental content threatens an intuitive right to privacy. How real and pressing this threat is and what should be done about it are important neuroethical questions. This chapter addresses the question of how to approach a neuroethical analysis of neuroimaging for brain reading or mind reading purposes. Doing so requires an evaluation of the science itself, in addition to consideration of the ethical issues. Studies of neuroimaging of deception are used as an illustration.

Good Science for Ethical Analysis

It is important to realistically assess what neuroimaging techniques can tell us when addressing the ethical issues of how neuroimaging data could, should, or should not be used, so is essential to understand the science behind the technique that generates the data in question. Thus, a neuroethical analysis of a potential neuroimaging threat to privacy involves two different kinds of investigations. One is a scientific assessment of precisely what kind of information can be revealed by the neuroimaging method and what kinds of inferences can legitimately be drawn from such information. It is important to understand the nature of the information, the range of possible interpretations of that information, the extent to which it can be reasonably generalized, and with what probability of error. The second aspect involves an ethical analysis of the proposed use of that information. This includes an inquiry into the ethics of obtaining that information and the ethics of its use, including whether and to what extent people have a right to keep that information private, and the circumstances under which other parties may be justified in procuring it. While it is possible to contemplate these ethical issues in a vacuum, it is not ideal, and our analysis may be led astray. Without an understanding of the nature and quality of the information at issue, the ethical analysis may fail to engage with the relevant scenario. Thus, the precise limitations of a technique may themselves have ethically relevant consequences.

Neuroscientific Analysis

Frequently, writers concerned with the ethical and legal implications of brain imaging tend to approach the science from one of two extremes. Some take an uncritical stance toward the ability of imaging to yield relevant information, quickly generalizing from crude studies or proof of principle to embracing the proposition that imaging can reveal precise mental content. Others focus so much on the limitations of the science that they fail to recognize areas in which the scientifically feasible yet imperfect study might be practically relevant. In discussions about the potential of fMRI to detect lies and/or deception, for example, one can find both extremes. A clear assessment of the ability of the techniques to reveal mental content in particular cases is an important element of the reasoning regarding the legitimacy or illegitimacy of its use.

Internal Validity

The internal validity of a study is the degree to which a conclusion based on the data is warranted. Because of the nature of the fMRI measurement and the amount of statistical analysis required to reach conclusions, there are many ways in which neuroimaging data can be misinterpreted or misanalyzed (see, e.g., the chapter on interpreting neuroimages in this volume). One worry is that if such errors are rampant in the field, then the body of literature on which applications of imaging rests may be unsound. Despite the attention that criticisms of neuroimaging methodology may have garnered (see, e.g., Vul et al. 2009), many studies are not flawed in these ways. Moreover, as techniques become more sophisticated and practitioners more aware of potential pitfalls, the quality evidence base for neuroimaging and the ability to identify which studies are part of this quality base will improve. Thus, no sweeping indictment of imaging is reasonable. However, even when brain imaging studies meet rigorous scientific criteria for basic research, the results of these studies may not be easily applied to real-world situations.

External and Ecological Validity

External validity concerns the extent to which scientific results can be generalized or applied to non-laboratory situations. Ecological validity concerns the extent to which the behavior studied in the laboratory mirrors the behavior of interest in the natural world. Because the interpretation of neuroimaging results in part depends upon comparing them to results of other imaging studies, or to generalizations based on other studies, the external validity of those studies is essential to assess. And because we often are interested in a naturally occurring phenomenon and try to discover its neural basis in the lab, it is also important to assess ecological validity. In what follows, the study of interest is termed the target study and the background data as comparison studies. The assessment of the external validity of neuroimaging studies is crucial in determining whether inferences based on brain imaging data are warranted, and assessment of ecological validity is important for determining whether such research can be applied in real-world settings. A number of the most significant factors to consider when making such assessments are discussed below.

What Is Being Measured in a Study?

Neuroimaging paradigms are not always what they seem, and researchers sometimes set out to study a phenomenon but end up designing a paradigm that unwittingly probes something else. In all cases it is essential to determine what is being measured in a study. Is it what the study reports it measures? Secondly, is what is being measured in the target study the same thing that is being measured in the intended comparison studies? If not, how are they related? Establishing this is important in order to assess the degree to which the target study can be interpreted in light of the intended background.

What Is the Population Studied? Is There Reason to Think It Differs from the General Population?

There is significant variability in neuroimaging results across different populations. Most basic research is carried out on normal, healthy college-age populations. One should always be aware of whether the target study involves a different population. Is there reason to think there will be systematic differences between responses of these populations? The answer may be no if the target study involves normal adults, but we know that there are significant age-related changes in brains of juveniles and the elderly. There may also be relevant differences among socioeconomic extremes. Moreover, some target studies may focus on particular populations that we have reason to think may have substantial neural differences from the norm, such as drug addicts, violent offenders, or people with psychiatric dysfunction (Brower and Price 2001). It has been reported that a large percentage of incarcerated populations have sustained damage to frontal areas and thus have brains that are significantly different from normal on a variety of measures (Brower and Price 2001). One has to be very careful about making inferences about the significance of deviations from normal activation patterns in such groups.

What Is the Error of the Measurement?

If using brain imaging for diagnostic or predictive purposes, it is important to understand error rates. However, error rates in many studies are not well defined and pose statistical problems discussed further below. In addition, using imaging for diagnostics requires that one have statistics about the baseline occurrence of a phenomenon of interest. Where this information is not available, true error rates may not be able to be assessed.

Are There Statistical Limits to the Application?

Brain imaging is noisy: many trials are averaged together in order to reduce noise so signal can be detected. Often trials are averaged among subjects, confounding differences in brain structure and functional anatomy with results. The poor signal to noise of fMRI makes it very difficult to apply in paradigms where repetition is difficult or impossible or where it alters the nature of the task.

Ethical Analysis

A number of ethical and legal considerations also impact whether and to what extent we should use the results of neuroimaging to reveal mental content. These considerations regard the manner in which that information is obtained and whether obtaining it infringes rights that are either fundamental or otherwise enshrined in the law. Below I discuss a number of issues that should be considered in an ethical analysis of neuroimaging.

Is the Data Obtained Ethically?

Harm

Obvious ethical questions concern the procedures of obtaining neuroimaging data. A first question is whether the process of obtaining the data results in physical harm to the subject. For example, some imaging or related techniques, such as those employing radiation (such as PET) or disrupting neural firing (such as TMS), may potentially, under some regimes, harm the subject. These harms in many cases would rule out the use of the technique and in other cases must be weighed against potential benefits. However, there is no evidence that techniques most frequently employed for brain reading, fMRI and EEG/ERP, pose any health threat.

Consent

A second question concerns consent. The ethical questions about using neuroimaging-derived information vary depending upon whether the information is obtained with or without consent. If a subject freely consents to a study, some worries are allayed. However, since some information can be gleaned without a subject's knowledge, even subjects consenting to be scanned may not have consented were they fully informed of the type of information to be gleaned. The potential of fMRI to yield information about some psychological aspect other than the one being overtly probed raises ethical questions about the effectiveness or legitimacy of standard consent practices.[1] Information of that sort should perhaps be treated as data obtained without consent, and when prior consent for this type of information is not possible, perhaps in such cases post hoc consent should be sought before the data is used.

In some potential uses of neuroimaging, such as in legal or employment contexts, consent may be coerced. In general, however, coercion is unlikely to be effective, because fMRI requires cooperation by the subject in several ways: subjects must remain very still in order to get interpretable data; slight head motion or even movement of the jaw or tongue can make scan data unusable. Secondly, most fMRI studies require that subjects perform a task, which also requires cooperation. Because of the practical necessity for cooperation, we are likely to see brain scans introduced much more in situations in which they could be potentially helpful to the subject. Thus, they are more likely to be introduced as evidence in exculpatory contexts in criminal cases or as evidence of truth telling rather than lying.

Of course, if a technique is to be used without consent, other questions arise. First, is the technique effective in a non-consenting subject? Second, can results be effectively subverted with countermeasures? Because neuroimaging is currently well-nigh impossible on a normal subject that does not consent at least to being the subject of an experiment, a variety of potential objections do not arise. One possible scenario, however, is that as we learn more about what can be gleaned by

[1] It should be noted that this is already possible to achieve with behavioral tests. Moreover, it is not clear that this information tells us anything about how a person will act in a certain situation. The biases, even if real, could be counteracted by other processes and never affect decision or action.

baseline or resting-state fMRI, certain things, such as disease states, may be discernable from scans that do not require active subject participation. Another notable exception arises when the subject is unable to consent, such as when the subject is in a state of diminished consciousness (see ▶ Chap. 41, "Detecting Levels of Consciousness"). In such cases, consent should be sought from a proxy.

Are There Alternative Methods for Getting the Same Data?

Often, if you want to know what a person is thinking, the best way to find out is to ask him. In many cases, this is preferable to trying to determine an answer through imaging. However, there are situations in which a consenting subject could not otherwise provide the sought-after information. In some cases, this information is not available to consciousness. Studies of bias using a number of behavioral paradigms probe such information. In other cases, such as in lie detection, subjects have an issue with credibility. Because the credibility of the subject is at issue, voluntary disclosure does not substitute for a measure that has the ability to detect deception. One then has to ask whether the neuroimaging ability to detect deception in the kind of circumstances at issue is sufficiently good for the purpose at hand. The scientific analysis is crucial here. Moreover, if it is more accurate than other available techniques, are there nonetheless reasons to prefer those other techniques? In legal settings, there is an abiding sentiment that juries are a more appropriate lie detection method than a scientific/mechanical one, even though the justification for this is rarely made explicit, and it is not clear that there is a defensible one. How good would a scientific technique have to be to substitute for a jury decision? Do the consequences in terms of perceived legitimacy, potential misuse, etc., require only that the technique be more reliable than jury decisions or much more so?

Is There a Right Being Violated?

Perhaps the central ethical issue raised by neuroimaging is whether it infringes upon a right. The standard worry is that brain imaging violates a right we have to the privacy of the contents of our thoughts. Until now, no techniques have been developed that accurately reveal mental content without behavior. Now the prospect exists for obtaining evidence for mental content without reference to behavior, whether voluntary or involuntary.

Privacy issues arise when someone other than the subject desires to procure information that the subject may want to keep private. Then one must answer the difficult questions of whether the person has a right to keep that information private and, if so, whether there is justification for infringing that right.

Is There a Right to Privacy?

Although a right to mental privacy is often taken to be intuitive, it is not clear whether there are deep principled reasons that undergird such a right or whether such a right is assumed simply because the mental content is by nature private, and breaching that privacy usually involves coercive techniques. The foundations for

such a right are not clearly articulated, though it is argued that privacy is a necessary protection for freedom. One's view of whether one has a right to the privacy of the contents of one's thoughts and the scope of such a right will likely depend at least in part on other ethical commitments. For example, utilitarians will probably have very different views about privacy rights than those with a more deontological bent.

As mentioned, although intuitively there is value to the first-person access one has to the content of one's own thoughts, the nature of that value is obscure. Little has been written philosophically defending the value of mental privacy, but as one aspect of what is sometimes called "cognitive liberty," it is frequently taken to be a fundamental right (see, for instance, http://www.cognitiveliberty.org/; Farahany 2012; Warren and Brandeis 1890). Alternatively, as Warren and Brandeis theorized, mental privacy can be thought of as an extension of common law property rights. They analogized thoughts to a creation of the thinker and recognized a right in the common law that gives to each author sole rights to his creation (e.g., thought) until he voluntarily communicates it to the public. "The common law secures to each individual the right of determining, ordinarily, to what extent his thoughts, sentiments, and emotions shall be communicated to others. Under our system of government, he can never be compelled to express them (except when upon the witness stand); and even if he has chosen to give them expression, he generally retains the power to fix the limits of the publicity which shall be given them." Warren and Brandeis have perhaps best articulated this implicit broad right to privacy for mental content and argued that mental content, regardless of how expressed, should be afforded the same protection. They continue, ". . .If, then, the decisions indicate a general right to privacy for thoughts, emotions, and sensations, these should receive the same protection, whether expressed in writing, or in conduct, in conversation, in attitudes, or in facial expression." It is but a small step to extend the same protections to mental contents that remain unexpressed.

Warren and Brandeis' argument is influential and perhaps compelling, but it is not law. There is no express right to privacy in the Constitution. The Bill of Rights, however, protects specific aspects of privacy, although in a piecemeal and less explicit way, protecting what Supreme Court Justice Louis Brandeis dubbed as a "right to be left alone," in Olmstead v. United States, 277 U.S. 438 (1928). The First Amendment protects certain freedoms, such as the freedom of religion, of the press, and of expression, prohibiting federal laws restricting these freedoms. The Amendment has been read broadly as protecting the privacy of beliefs, but whether these protections would be extended to mental states discernable by neuroimaging technologies has not been explored in the case law. At a theoretical level, first amendment rights may not appear to be directly applicable to neuroimaging scenarios, for they concern freedom of expression. Nothing about neuroimaging, which is a measuring technique, interferes with expression, nor does imaging involve any sort of manipulation or restriction of thought content. However, the courts have come down strongly not only on measures that restrict expression but also on those that can have a "chilling effect" on expression.

Because it is very likely that if neuroimaging could be used to discern the contents of thoughts against a person's will, it would have a chilling effect not only on expression but also on the source of expression, and thus it would impact the freedom people have even to entertain those thoughts. It is here that First Amendment protections would most likely come into play.

While the First Amendment protects expression and belief, the Fourth Amendment protects the right of citizens to be secure in their persons and effects against unreasonable searches and seizures. It is no stretch to imagine that brain scanning without consent, for instance, would constitute an unreasonable search, and even potentially that mental content revealed could be considered property, as Warren and Brandeis have argued. The Fifth Amendment protects persons against self-incrimination, preventing the state from using a person's own knowledge against himself. The uncertain status of imaging as physical or testimonial evidence will be crucial here, for if it is seen as physical evidence, the protection does not apply. The Fourth and Fifth Amendments thus have the potential to provide for a privacy of the mental insofar as mental states are aspects of persons abut which expectations of privacy are reasonable or are testimonial and can be incriminating.

These rather circumscribed areas of privacy rights are arguably significantly broadened by the Ninth Amendment, which states that the people retain rights not necessarily enumerated in the Bill of Rights. However, what those rights are, if there are any, is highly disputed. Finally, the Fourteenth Amendment extends the protections in the Bill of Rights against infringements by the states. The Due Process clause of that amendment mandates that the states do not deprive citizens of life, liberty, or property without due process of law. The liberty interests thus protected have been interpreted by the courts to include a variety of substantive freedoms such as the right of contract and right of privacy in one's home and relations, and in the last decades substantive due process has been extended to many other aspects of personal life. Sometimes also glossed as the "right to be left alone," this aspect of the Fourteenth Amendment may arguably ground a more extensive domain of privacy than any previously discussed.

Is It Absolute and Inviolable or Is It a Presumption That Is Weighed Against Other Considerations?

In the law, these privacy rights, and by extension privacy afforded to mental content, are not inviolable, but are weighed against the needs of the state. Moreover, while legal strictures against infringement against freedom of expression are stringent, requiring strict scrutiny, those regarding private property are less so. Thus, even though the law recognizes that aspects of privacy deserve to be protected, those protections are not absolute and privacy can be infringed given sufficient reason. Given the recent revelations about the scope of government surveillance on citizens and foreign nationals, it has become a matter of much debate how we should weigh privacy rights against other rights and the needs of the state. Clearer articulation is needed of the importance of privacy, both as an end in itself and, instrumentally, for the preservation of other values.

Application: Detection of Deception

To illustrate the above concerns, one prominent potential use of neuroimaging of mental content is discussed: whether laboratory studies of lie detection ground the applicability of fMRI lie detection for real-world applications.

Scientific Analysis

External and Ecological Validity

There is no doubt that neuroimaging can provide some information relevant to lie detection or detection of deception (Christ et al. 2009; Hakun et al. 2009; Kozel et al. 2005). Numerous studies demonstrate that a constellation of brain areas is more active during deception than during non-deceptive responding in these paradigms. Despite this, recent meta-analyses show that although deception reliably activates a number of brain areas relative to truth telling, there is considerable variability across studies, and no regions were found to be activated in all studies (Christ et al. 2009). There is thus no specific fMRI brain signature of deception. Furthermore, there is reason to question whether these methods probe mental content at all: these paradigms may not isolate neural changes reflective of the phenomenon of lying itself or even of the intent to deceive and may instead reflect brain activation that merely co-occurs regularly with deception (such as, e.g., emotional arousal, salience, etc.). For discussion of a number of experimental confounds, see Farah et al. (2014). While mere correlation may suffice for some purposes, for others – such as determining whether fMRI indications of deception is more like physical evidence or testimony, an important question regarding the constitutionality of fMRI lie detection in court – it cannot. Finally, there are significant reasons to question the applicability of fMRI lie detection to practical situations, such as legal contexts (Langleben and Moriarty 2013; Wagner 2010; Wolpe et al. 2005).

Perhaps the main problems with experiments on lie detection have to do with whether the paradigms used in extant studies really probe or measure the phenomenon they purport to measure: lying or deception. Many of the studies employ paradigms in which subjects are instructed to lie. In some, they are instructed to lie about a particular issue (i.e., lie when queried one of two cards they hold (Davatzikos et al. 2005; Langleben et al. 2005)); in others they are told to lie about a number they picked (Hakun et al. 2008) or are cued to lie or tell the truth about a question (Ganis et al. 2003); in still others they are instructed to perform an act and then lie about it (i.e., “steal” a ring or watch, then lie about having done it) (Kozel et al. 2005). However, in all these cases, it is questionable whether the subjects are really engaging in deception or are better thought of as complying with instruction. This illustrates the difficulty in designing studies that incorporate ecologically valid deception tasks. Perhaps the only extant study not subject to this worry is one in which subjects are not instructed to deceive and instead are merely given the

opportunity to do so, and when they do, they do so out of their own motivation believing that they are gaming the system. In this study by Greene and colleagues, subjects are told to report the outcomes of blind coin tosses, in a money game. Deceptive subjects are identified on the basis of improbable winnings (Greene and Paxton 2009). This is likely the most ecologically valid of the deception studies; its limitation is that the outcomes of individual trials are unknown, so individual subject behavior can only be determined statistically, across many trials. While there are differences in overall brain activation patterns between subjects who lie more often and those that lie less, these differences cannot be determined on a trial by trial basis, and they may be due to factors that correlate with the tendency to deceive, such as, for instance, particular character traits, but not with deception itself.

A more subtle issue about what is being measured is illustrated by some lie detection paradigms. In some studies, the conditions in which subjects are instructed to lie tend to occur infrequently and involve the detection of a target. For instance, an instruction to "lie when the Queen of Hearts comes up" may seem like a lying task, but it may better be described as a detection task for the Queen of Hearts, rather than a lying task (Emilio Kanwisher's contribution in Bizzi et al. 2009). Indeed, the dynamical brain signatures of such tasks look much like oddball detection paradigms that do not involve lying (Rosenfeld et al. 2008). Thus, a study may masquerade as a lie detection task but may in fact measure a quite different psychological phenomenon.

Finally, a variety of contextual factors differ between laboratory settings and real-world settings in which lie detection technologies would be most useful. The stakes in real-world settings are much higher than in the lab, and this can generate emotional reactions not present in experimental settings. Many of the brain areas involved in emotional response and regulation are precisely the ones that display differences in lie detection imaging results, leading to the possibility that using fMRI lie detection paradigms (or, for that matter, other physiological measures) in realistic situations will generate a significant number of false positives.

Population Differences

Another reason to be suspicious of the external validity of lie detection paradigms is that the population that these studies draw upon differs significantly from the populations upon which lie detection devices are most likely to be used. As noted before, fMRI research studies tend to use college students; lie detection technologies are most likely to be used in forensic contexts or in personnel screening. The demographics of these populations are much different. Whether results from college students would be representative of or extendable to these diverse populations is unknown.

Errors and Statistics

There are also significant statistical limitations to using the data from lie detection experiments in real-world situations. Applications of lie detection methods generally aim to determine whether the response of an individual to a particular question or about a particular issue is a lie. Thus, the utility of these techniques depends upon

being able to distinguish lies from sincere responses for individuals on individual trials or items. However, the vast majority of lie detection studies that could be used as comparison tasks rely upon data averaged across multiple subjects, each of whom had undergone multiple trials. Moreover, most studies report areas consistently activated across subjects, but do not report individual subject data. This provides a prima facie barrier for using this information for identifying lies in individuals or on individual trials. The few studies that attempt to determine whether individuals are lying on specific trials (Davatzikos et al. 2005; Langleben et al. 2005) report lower accuracy than group studies and suffer from experimental design confounds making these figures suspect (Farah et al. 2014).

Finally, an underappreciated factor may be a significant barrier to understanding the diagnostic power of neuroimaging for lie detection. Although several companies have already begun to offer lie detection services to consumers, touting their accuracy, it is not possible to estimate the actual diagnostic power of the technique without an understanding of how prevalent lying or deception is in the populations of interest. For example, No Lie MRI advertises that their technique is over 90 % accurate and estimates that in the future accuracy may reach 99 % (http://www.noliemri.com). But these predictions are misleading. Knowledge of base rates and the specificity and sensitivity (rates of false positives and false negatives) of methods is needed to provide a full picture of how good a technique is. Few studies report the sensitivity and specificity of the methods, and when they do, they are relative to the laboratory test. Whether error rates associated with a diagnostic method is acceptable will depend upon the base rate of lying, and no measure of base rates for lying is available, nor is it clear how it could ever be. Furthermore, even if one could determine base rates for lying, what would be the relevant population and context for which the base rate should be determined? Would it be the general rate of lying in the public? The rate of lying for people charged for a crime and undergoing lie detection? The rate of lying in the prison population?

Without knowledge of base rates and error rates, the predictive accuracy of these techniques cannot be determined. Indeed, in two recent court cases (US v Semrau 2010; Wilson v. Corestaff Services 2010), the courts decided against admitting neuroimaging evidence for lie detection. Because of unknown error rates and worries about the ecological validity of the laboratory tests, neuroimaging for lie detection was deemed not to pass the Daubert or Frye standards for scientific evidence.

Ethical Analysis

Harm and Consent

Typical neuroimaging paradigms are not harmful and require the cooperation of the subject. However, to the extent that they can be used to discriminate familiar from unfamiliar information with passive viewing, they could potentially be used without the subject's knowing what they are in the scanner for. This may be considered a use without consent, which raises an ethical flag.

Privacy

Does the use of neuroimaging for lie detection infringe on privacy rights? Certainly neuroimaging can provide information in which people could have a clear privacy interest, such as in health-related information mentioned in the introduction. These concerns are real, but they are not significantly different from the concerns raised by genetic and other personal information, and there are already models in the health sciences for dealing with these issues through HIPPA and related doctrines. Recently, some heightened concerns regarding anonymity have arisen with regard to genetics because it has been shown that in some circumstances enough information can be gleaned from anonymous genetic data to determine the person from whom it came (Gymrek et al. 2013). However, thus far there is little reason to think that brain imaging data will present the same kind of threat of carrying covert identifying information that genetics does: although our brains are certainly unique, there are no analogs here to heritability and surname inheritance to aid in identification, and we lack information about brain function at a fine-grained enough level to ground identifying inferences between brain data and personal characteristics.

What makes neuroimaging of deception potentially threatening is not just the dissemination of personal information; it is the specter of abolishing the privacy of the mental. With regard to First Amendment protections, one should ask whether lie detection poses a threat to freedom of expression or belief. Since it does not restrict expression or prohibit any beliefs, it is unlikely that imaging will be prohibited for that reason; it is also not likely that the prospect of lie detection would be considered to have a chilling effect on protected speech. Some paradigms, such as the guilty knowledge paradigm (GKT), which aims to distinguish brain activations to familiar and unfamiliar stimuli, may abridge privacy rights. Fourth Amendment protections could be invoked to prevent the state from imaging a person without their consent, as this may be thought to constitute unreasonable search of a person's person or property. However, with current technology, it is very difficult to image a noncooperative subject, so it is unlikely that this defense will prove necessary in the short term. Fifth Amendment protections might also be invoked: there is an interesting theoretical question about whether neuroimaging data is like physical evidence (such as fingerprints and blood alcohol level), and thus not protected by the Fifth Amendment, or like testimony, and thus should enjoy Fifth Amendment protections (see, e.g., Farahany 2012; Fox 2008; Gymrek et al. 2013; Holley 2009; Hurd 2012; Stoller and Wolpe 2007). However, the scientific limitations of lie detection technologies and the difficulty of applying them in real-world situations make it unlikely that any of these protections will need to be invoked any time soon, because these techniques are not yet admissible in court. Thus, at least for the foreseeable future, it seems that privacy concerns are not going to be the ones that limit the use of neuroimaging; concerns about accuracy and applicability will be.

One area in which lie detection seems promising, is for use in exculpation. First, if imaging is used in order to exculpate, coercion and privacy concerns are further negated. More importantly, although the limited accuracy of lie detection and questions about its diagnostic power are reason to preclude its use in inculpating contexts, the statistics are in its favor for providing some support for indicating

absence of lying. Moreover, it is worth asking about the relative costs of error: given our presumption of innocence and the violence to our values done by convicting the innocent, a false negative (finding a guilty person innocent) is arguably more tolerable than a false positive (finding an innocent person guilty). Thus, it may be reasonable to hold imaging to different standards of accuracy depending on the context (Schauer 2010). Thus far, it seems that courts are unwilling to admit lie detection evidence even in exculpatory contexts, perhaps because of the prospect of the slippery slope that may lead to them being admitted in inculpatory contexts, where the statistics are not in their favor.

Conclusion and Future Directions: Mind Reading More Broadly

For illustration this chapter focused specifically on uses of lie detection. This is not ideal as a paradigm for privacy of mental content, since it is unclear whether lie detection methods even probe the content of thoughts. However, it is the only arena to date that is arguably related to mind reading in which significant work has been done geared toward potential use in real-world applications. Even so, for the numerous reasons here discussed, current technology is not sufficiently well developed to use lie detection for incrimination or even for screening. In other kinds of work, privacy issues may be raised much more clearly. There are increasingly effective attempts in the laboratory for identifying elements of mental content, such as what object a person is thinking of or even what visual scene they are experiencing. While the ability to reconstruct visual perceptual experiences from data garnered while they are being experienced is fairly impressive (Kay et al. 2008; Naselaris et al. 2009; Nishimoto et al. 2011), these methods do not do particularly well with memory reconstruction or identification of abstract thought. For the most part, current methods only allow inferences about rather coarse-grained content, and we are far from being able to reconstruct determinate propositional content (see Roskies forthcoming). Whether thought content, in all its richness and subtlety, could ever be a realistic target for imaging remains to be seen. Moreover, the successes thus far have been successes with a cooperating subject. There is scant evidence that mental content in any detail can be determined without cooperation of the subject. Thus, current methods are far from allowing determinate mental content to be gleaned from a non-consenting subject (Roskies forthcoming), reducing the potential range of scenarios that are most ethically challenging. If this should change appreciably, however, we will have to revisit the privacy issues sketched above in considerably more detail.

Ethical Implications of Brain–Computer Interfacing

Ethical Implications of Brain–Computer Interfacing

43

Jens Clausen

Contents

Abstract

Brain–computer interfaces enable direct brain-to-computer communication circumventing peripheral nerves and muscles. These devices offer promising clinical applications for a broad range of patients. This paper presents a brief overview of different BCI applications and ethical issues raised by these devices, and gives an introduction to this section containing four chapters focusing on the ethical aspects of BCIs for communication, for motor prosthetics, in ADHD patients, and in psychopathy, respectively.

Introduction

Connecting brains to computers usually relies on peripheral nerves and muscles as well as keyboards or other input devices like a computer mouse. Direct brain-to-computer communication bypassing peripheral nerves and muscles—for a long time a topic of the science fiction genre—is now possible through brain–computer interfaces (BCI). Miniaturization of microelectronic components and continuous progress in brain research together with an ever better understanding of the human

brain enables unprecedented direct brain-to-computer communication. The papers of this section briefly introduce different BCI approaches and discuss key ethical questions related to this technology.

Brain–Computer Interfaces

Usually, a BCI records neural signals from the brain or parts of it and uses these signals for controlling an external device. In general, three parts constitute a BCI: First, an internal interface enables signal acquisition, second, processing of these signals is carried out through algorithms in a central computing unit, and third, an external interface ensures contact to the surroundings via a specific output device (Wolpaw et al. 2002; Clausen 2008; van Gerven et al. 2009). Depending on the exact shape of these components, BCIs differ significantly (Berger et al. 2007) and may be used in a vast variety of diverse applications (Mak and Wolpaw 2009). These include assistive technologies like spelling devices for the severely paralyzed (Birbaumer et al. 1999; Birbaumer and Cohen 2007), motor prostheses for paraplegics (Hochberg et al. 2012; Collinger et al. 2013), neurorehabilitation for stroke patients (Buch et al. 2008), and a BCI-controlled wheelchair (Leeb et al. 2007; Galán et al. 2008). BCIs might also be used outside the clinic. While developed for creative expression in paralyzed patients (Munssinger et al. 2010; Zickler et al. 2013), BCI brain painting is already used by artists (pingo-ergo-sum.com). Controlling computer games also seems a possible application of BCIs (Liao et al. 2012). This section, however, focuses on clinical BCIs and their ethical implications.

Ethical Implications

While BCIs promise various benefits for different groups of patients, these devices also need an ethical examination. The ethical discussion started about 10 years ago and addresses a broad range of issues including quality of life, responsibility and liability, the notion of autonomy in using such devices, personal identity, and questions of enhancement when used beyond the realm of therapy (Clausen 2006, 2008, 2009, 2011; Johansson 2008; Lucivero and Tamburrini 2008; Haselager et al. 2009; Tamburrini 2009; Vlek et al. 2012).

A recent special issue in *Neuroethics* (Clausen 2013) and a report from the Nuffield Council on Bioethics (Baldwin et al. 2013) present a comprehensive overview on neurotechnologies including stimulating devices and their ethical implications. This section of the Handbook of Neuroethics addresses the ethical implications of BCIs for communication, motor control, BCI in attention deficit hyperactivity disorder (ADHD), and also BCI approaches in Psychopathy.

Surjo Soekadar and Niels Birbaumer focus their paper on brain–machine interface-based communication especially in complete paralysis like the locked-in state. They present an introduction to the different technological approaches of brain–machine or brain–computer interfaces followed by current technical

challenges in the use of BCI for paralyzed patients like the high rate of false-positive and false-negative classifications and the missing evidence for BCI control in the complete locked-in state (where no residual voluntary motor control is left). This might suggest a fundamental problem of learning and attention. While fragmentation of sleep challenges BCI performance especially with respect to hitting the right time for recordings, the hypothesis of the extinction of goal-directed thinking due to the lack of reinforcing feedback presents a more fundamental challenge. If this hypothesis is true, it might be difficult if not impossible to establish BCI-based communication with patients in the complete locked-in state. However, implementing classical semantic conditioning into a metabolic BCI based on near-infrared spectroscopy might be a promising alternative. Soekadar and Birbaumer identify and discuss ethical implications of BCI-based communication in paralysis with respect to questions of informed consent, advance directives, and quality of life. They point to evidence that physicians and relatives usually underestimate these patients' quality of life. This might also be true for the patients themselves when in a premorbid stage anticipating the quality of life in a locked-in state, which might challenge the validity of end-of-life decisions in such advanced directives. Against the backdrop of high rates of misdiagnosis in disorders of consciousness, the authors recommend EEG monitoring and the use of BCI systems in behavioral unresponsive patients for detecting possible remaining awareness.

Donatella Mattia and Guglielmo Tamburrini focus their investigation on the ethical implications of BCI systems for motor control. They address the ethical challenges of these devices around five conceptual frameworks: first informed consent and respect for persons, second beneficence, justice, and autonomy, third responsibility and liability, fourth liberty, and fifth responsible communication of BCI research. The authors concede that these ethical issues are not unique questions raised by BCIs but are well known from other fields of neuroethics and biomedical ethics as well. However, Mattia and Tamburrini identify three aspects in the field of BCI research, which recommend a closer look at the mentioned ethical issues. *Brain–computer mutual adaptation* points to the fact that BCI operation involves two adaptive controlling units: the central nervous system and a computer algorithm. *Machine intelligence* describes the need for autonomous intelligent action of BCI-controlled devices at least to some degree. The third aspect emphasizes the restricted class of *potential users* of BCI devices for motor control. Persons affected by severe motor impairments are most likely to benefit from this kind of technology, while those who are less affected and kept the ability to some voluntary movements might prefer alternative assistive technology.

Imre Bard and Ilina Singh introduce attention deficit hyperactivity disorder (ADHD) and BCI-neurofeedback followed by a summary of today's knowledge on BCI-neurofeedback in ADHD. In the current state of limited knowledge and contradictory results, they identify safety and efficacy as key elements for the ethical discussion in this field of BCI technology. Against this backdrop, they address questions of regulation and commercialization, responsible communication and neuroliteracy, identity, and the use of BCI for performance enhancement. Bard and Singh emphasize two different but interrelated challenges:

commercializing BCI-neurofeedback systems often without sufficient scientific evidence of their efficacy and the lack of regulatory oversight. Both might be held especially problematic when this method is used for toys, games, and educational aids specifically targeted at children with ADHD. The authors conclude by pointing out the importance of further targeted research in this specific field and the need for responsible communication.

Fabrice Jotterand and James Giordano address potential challenges in using BCIs for the assessment and treatment of psychopathy. Given the lack of effective psychopharmacological treatments for psychopathy, the authors welcome the opportunity to investigate the possible utility of BCI technology in this field. A brief introduction to psychopathy and the limited diagnostic tools for these patients is followed by a discussion of potential ethical concerns with an emphasis on questions of personal identity.

Conclusion and Future Directions

Brain-computer interfacing presents exiting research directions at the overlap of neuroscience, micro-electronics, nanotechnology and the clinic. While BCIs promise unprecedented insight in and a better understanding of the brain and it functions they also raise important ethical questions. The ethical questions discussed in the contributions to this section present a comprehensive overview of the ethics of BCI technology to accompany its development. Neuroscience together with ethical considerations will enable to realize the full potential of this technology inside and outside the clinic to improve quality of life and provide innovative directions in arts, gaming and probably other areas of daily living.

Brain–Machine Interfaces for Communication in Complete Paralysis: Ethical Implications and Challenges

44

Contents

Abstract

Recent advances in computational capacities and sensor technologies allow online translation of electric, magnetic, or metabolic brain activity into control signals of computers or external devices. These brain-machine or brain-computer interfaces (BMI/BCI) allow individuals with complete paralysis to sustain communication, for example, enabling them to answer simple "yes-no" questions or to select letters in order to spell out whole words and phrases. The possibility to sustain communication through BMI/BCI systems in paralysis raises many critical neuroethical questions addressed in this chapter.

After an introduction and overview of the available BMI/BCI systems used for communication, ethical implications of this novel technology are drafted and discussed in direct reference to results and new insights from several clinical studies. These suggest, for example, that quality of life in locked-in syndrome (LIS), a state in which an individual is unable to move or speak, is not as limited and poor as generally believed, so that "patient wills" or "advanced directives" that were signed long before the locked-in state are questionable and might be used to avoid financial and social burdens by shortening what is anticipated to be long periods of care. After discussing limitations and challenges of the current BMI/BCI technology, the chapter closes with a future outlook and perspectives.

Introduction

Since its first conception by Jacques Vidal in the early 1970s (Vidal 1973), much work has advanced toward realization of direct brain communication via brain-computer or brain-machine interfaces (BCI/BMI), allowing communication without the involvement of the body. Following the ideas of Austrian novelist Ludwig Hohl (1904–1980) that "the human being lives according to its communication capacity" (Hohl 1984), the possibility of disembodied communication, which extends conventional means of how humans interact with their environment, might appeal to our fantasies of grandeur, but becomes existential once these conventional means have been lost, as "loosing the capacity for communication means loosing life" (Hohl 1984).

The development and applicability of BMI/BCI systems has been primarily driven by improvements in computational capacities and sensor technology, allowing for the instant translation of electric, magnetic, or metabolic brain activity into control signals or commands of computers and external devices (Birbaumer and Cohen 2007). The abbreviations BCI and BMI are synonymously used in the literature; however, authors dealing with neural interfaces controlling prosthetic devices or robots generally prefer the latter (Wolpaw and Wolpaw 2012). It is conceivable that the next few decades will see substantial shifts of current technical frontiers, while some concrete scientific problems are still unsolved. It is foreseeable, though, that the feasibility to communicate with severely paralyzed or behaviorally unresponsive individuals entails ethical implications, urging for a broader interdisciplinary discourse.

Such discourse, however, requires some basic understanding of the technical and scientific state-of-the-art, and must consider medical, legal, and often also cultural aspects of the societies in which this technology is used.

The first BCI systems providing real-time detection of brain events date back to the late 1970s (e.g., Vidal 1977) and take advantage of the early observation that electric brain potentials and oscillations first described by Hans Berger (1929) that show event- or task-related modulations, e.g., in preparation of a movement (Gastaut 1952), when solving a mental task (Klimesch 1996) or in preparation or reaction to an external stimulus (Chapman and Bragdon 1964). These modulations were topographically specific, so that the modality of brain function that was "engaged" during a specific

time interval could be identified. In 1999, Niels Birbaumer and his group at the University of Tübingen were the first to use such a system, which they called "thought translation device" (TTD) in two patients suffering from amyotrophic lateral sclerosis (ALS) (Birbaumer et al. 1999), a neurological disorder that leads to degradation of upper and lower motor neurons, often resulting in complete paralysis. These patients suffered from locked-in syndrome (LIS), a term introduced by Plum and Posner in 1966, referring to a neurological condition characterized by quadriplegia, lower cranial nerve paralysis, and the inability to talk, whereas consciousness and the ability to perform eye blinks remains intact (Plum and Posner 1966). By providing an alternative communication channel for this paralyzed patient, availability of BCI systems raised notable enthusiasm that even when the patient's ability to perform eye blinks or any other muscle twitches has vanished, a state termed complete locked-in syndrome (CLIS), such technology would still help sustain the patient's ability to communicate (Wolpaw et al. 2000). This perspective seemed particularly relevant as larger studies with individuals in LIS who were chronically respirated and artificially fed indicated that their quality of life was higher than expected (Lulé et al. 2013; Kübler et al. 2005a, 2006, Kübler and Birbaumer 2008) and their will to live largely uncompromised.

But where are we today? Despite innumerous experiments resulting in hundreds of scientific papers, no single scientifically documented patient with complete locked-in syndrome (CLIS) has ever been able to re-establish communication using a BMI/BCI. This suggests a more fundamental theoretical problem of learning and attention in advanced stages of ALS, as formulated in the extinction-of-thought hypothesis. At the same time, a larger multicenter clinical study using functional magnetic resonance imaging (fMRI), a technique to quantify task-related changes of blood-oxygenation level dependent (BOLD) signals, indicates that the rate of misdiagnosis in patients with disorders of consciousness ranges at approximately 30–40 % (Monti et al. 2010). Patients who are behaviorally unresponsive and become diagnosed as being in a vegetative or minimally conscious state show signs of wakefulness such as periodic eye opening and closing, but no signs of awareness. However, this recent study has demonstrated that they might in fact be well aware of their environment, and thus misdiagnosed. Recent work has shown that, for example, two patients with traumatic head injuries who were diagnosed as being in a minimally conscious state (MCS) and one patient diagnosed as in a vegetative state (VS) for 12 years were able to guide their attention to repeatedly communicate correct answers to binary "yes" or "no" questions by modulating their metabolic brain activity (Naci and Owen 2013).

These and other study results have brought to light a variety of scientific and ethical problems that were not expected before. For example: Are patients, relatives, and care-givers sufficiently informed about quality of life in complete paralysis and the possibilities of sustained communication via BMI/BCI technology when formulating advanced directives or patient wills? Which steps are important in the process of informed consent related to the application of BMI/BCI technology? Can a patient perform legal acts or ultimately decide on ending life support using a BMI/BCI system? How should we deal with advanced directives signed long before the present state of a disease?

After giving a general overview of currently established invasive and noninvasive BMI/BCI systems for communication and summarizing several clinical studies, this chapter strives to introduce some major ethical challenges, opening a discussion on possible perspectives on how these new technologies might fit into daily clinical practice.

Brain-Machine Interfaces for Communication

BMI/BCI systems rely on the detection, classification, and interpretation of brain activity, which can be recorded from sensors inside or outside the skull. Depending on the site of recording, BMI/BCI can be categorized as invasive or noninvasive systems (Wolpaw 2007). Other categorizations relate to the specific brain signal used for BMI/BCI control or the mode of operation. In terms of operation mode, active, passive, and reactive BMI/BCI applications can be distinguished. While active and reactive (also "evoked") BMI/BCI require the user's full attention to generate voluntary and directed commands, passive BMI/BCI relates to the concept of cognitive monitoring, introducing the assessment of the users' intentions, situational interpretations, and emotional states (Zander and Jatzev 2012).

In active BMI/BCI applications, two forms of control can be distinguished: synchronous and asynchronous control (Müller-Putz et al. 2006). In synchronous control, translation of brain activity follows a fixed sequence or cue, often indicated by external stimuli. Brain control is only possible during these fixed time intervals, and users are asked to rest in between the control trials. The main advantage of this design is that it allows for continuous calibration of the BCI/BMI system so that "active" and "rest" states can be reliably discriminated, even if, due to the non-stationarity of brain states, features of brain physiology vary during rest, e.g., due to fatigue. In asynchronous or un-cued control, the user has continuous control. Both operation modes have advantages and disadvantages depending on the purpose of the use, and it is conceivable that even a combination might be desirable in certain applications. For instance, using an asynchronous "brain switch" to start BMI/BCI control (based on a non-ambiguous brain signal that does not require continuous calibration or comparison with an unstable "rest" state), followed by a synchronous mode for communication (Pan et al. 2013).

The following paragraphs will introduce the best established and tested BMI/BCIs, with particular emphasis on those that were already successfully used for communication in patients with paralysis.

Noninvasive BMI/BCI

Since the discovery that electric or magnetic brain oscillations contain information about cognitive states (Ray and Cole 1985), which can be functionally specific (Chatrian et al. 1959; Walsh 1953), the idea to use such signals for direct brain control of assistive machines has become a major driving force for the development of BMI/BCI technology (Wolpaw et al. 2002).

The following noninvasively recorded neurophysiological signals were successfully used to control assistive devices in individuals with paralysis: (1) slow cortical potentials (SCPs) (Birbaumer et al. 1990, 1992), (2) sensorimotor rhythms (SMR) and their harmonics (Kübler et al. 2005b; Soekadar et al. 2011), and (3) event-related potentials (ERPs), e.g., P300 (Sellers and Donchin 2006; Nijboer et al. 2008) or steady-state visual evoked potential (SSVEP) (Müller-Putz et al. 2005).

Use of SCP in BMI/BCI applications goes back to Niels Birbaumer and his coworkers' work in the late 1970s showing that operant control of SCPs in healthy volunteers is possible (Lutzenberger et al. 1982). Later, such control enabled a paralyzed ALS patient to select single letters on a computer screen spelling to write entire text paragraphs (Birbaumer et al. 1999, 2003; Perelmouter and Birbaumer 2000; Wolpaw et al. 2002). Up to now, over 40 individuals with ALS at various stages of their disease have been trained to use such SCP-BCIs, with 7 of them in LIS. However, attempts to train a person after transitioning into CLIS, once any voluntary muscle twitches vanished, were unsuccessful (Hinterberger et al. 2005; Wilhelm et al. 2006; DeMassari et al. 2013a). The finding that any instructions to have specific thoughts or imaginations did not result in any measurable physiological (brain) response later gave reason to the extinction of thought hypothesis (Kübler and Birbaumer 2008; Birbaumer et al. 2014).

In contrast to SCPs, sensorimotor rhythms (SMRs) are recorded over the sensorimotor cortex usually at a frequency of 8–15 Hz. Depending on the context, SMR is also termed μ-rhythm or rolandic alpha, and disappears (*desynchronizes*) during planned, actual, or imagined movements (Gastaut 1952; Howe and Sterman 1972). SMR modulation during a given time interval can be quantified as event-related desynchronization (ERD) and synchronization (ERS) (Pfurtscheller and Aranibar 1979), a measure that later became extensively used for synchronous (externally cued) BMI/BCI control. While SMR *desynchronization* (the relative decrease of synchronously active neuronal cell assemblies) seems to reflect widespread information processing within the sensory-motor system (Leocani et al. 2001), SMR *synchronization* seems to reflect synchronous idling of sensory-motor networks (Pfurtscheller et al. 1996). Use of SMR-modulation for BMI/BCI control was extensively investigated by the Pfurtscheller group in Graz (Pfurtscheller and Neuper 2006), the Wolpaw group in Albany (Wolpaw and McFarland 2004; Wolpaw 2007), and the Birbaumer group in Tübingen (Mellinger et al. 2007; Soekadar et al. 2011).

Another well-established and tested brain signal used for BMI/BCI control is the event-related potential (ERP), e.g., the steady-state visual evoked potential (SSVEP) (Müller-Putz et al. 2005) or P300 as introduced by Donchin (Farwell and Donchin 1988). ERP-BCIs quantify the response of the brain to an external stimulus ("externally evoked response"). While SCP and SMR control often requires multiple training sessions for reliable control, ERP-BCIs basically do not require any training. In the classical P300-ERP-BCI paradigm, a letter matrix is presented on a visual screen. The user is instructed to select one of the characters by focusing on it, while the letters start flashing in a random order. Every time the selected letter flashes, a P300 response (a positive potential shift recordable

approximately 300 ms after the stimulus) can be detected, allowing to infer which of the letters was selected by the user. Besides visual stimuli, also other sensory qualities such as tactile (van der Waal et al. 2012) or auditory stimuli (Furdea et al. 2009; Schreuder et al. 2010) were successfully implemented in P300-ERP-BCI. SSVEP-BCI evaluates the continuous visual cortical response evoked by repetitive stimuli of a specific frequency. As perception of flickering visual stimuli results in SSVEP of the same frequency and its harmonics, evaluation of SSVEP provides information about the user's visual attention, e.g., whether the user is attending the flickering stimuli or not. In such paradigm, detection of an SSVEP at a specific frequency becomes linked to a certain computer command. For instance, an SSVEP at 20 Hz indicates opening of a robotic hand and an SSVEP at 7 Hz closing. By giving the user the possibility to fixate one of two LED displays flickering at 20 and 7 Hz, respectively, evaluation of the SSVEP allows for one to infer whether the user intends to open or to close the robotic arm (Sakurada et al. 2013).

Information transfer rates (ITR) can reach over 100 bits/min using SSVEP-BMI/BCI, or 20–30 bits/min in ERP-BMI/BCI, compared to 1–5 bits/min in SCP- and SMR-BMI/BCI systems. ERP-BMI/BCI systems depend on an intact sensory system. Most neurological disorders that lead to LIS or CLIS, however, are associated with degradation of the sensory capacities (Weis et al. 2011; Lulé et al. 2010). For instance, most ALS patients in more advanced stages of the disease suffer from compromised eyes which are constantly dry over time, impeding the applicability of assistive systems based on eye gaze control (Lorenceau 2012) or pupil responses (Stoll et al. 2013). For these individuals, pre-assessment of the intactness of afferent pathways is essential before any attempt to use ERP-based BMI/BCI systems. The auditory modality seems the most promising modality after onset of complete paralysis, although auditory BMIs are underrepresented in the BMI/BCI research field as their performance is below visual-BCI-tasks (Nijboer et al. 2008).

Most recently, a blood oxygenation level dependent (BOLD) signal-based real-time fMRI (rtfMRI) system has been introduced for BMI/BCI control (Weiskopf et al. 2003; Yoo et al. 2004; deCharms et al. 2004; Caria et al. 2012). As intracortical activity is highly correlated with local blood flow change and the BOLD signal (Logothetis et al. 2001), such signal changes associated with differential cortical activations, e.g., during motor imagery, can be used for affirmative or negative brain responses following specific questions or letter spelling (Sorger et al. 2012).

One of the most appealing features of brain metabolic responses, such as BOLD, for brain communication in LIS is the superior learning curve when controlling these responses compared to neuroelectric or neuromagnetic activity. This might relate to the ability for more specific targeting of functional areas using metabolic BMIs compared to noninvasively recorded electric or magnetic activity that reflects activity of large and widespread cell-assemblies. In other words, identification of task-related BOLD responses seems more accessible due to their relatively high functional specificity compared to identification of event- or task-related activity from ongoing and chaotic electromagnetic activity. Another explanation is that the mechanisms underlying self-regulation of vascular changes within brain tissue

differ from those involved in modulation of electro-chemical activity and are more accessible to volitional control.

While SCP regulation and selection of letters on a computer screen based on SCP changes in LIS (Birbaumer et al. 1999) and patients with intractable epilepsy required 30–100 sessions of intensive skill training, control of BOLD response was acquired within a few trials. For instance, rtfMRI of the cortex (deCharms et al. 2004, 2005), Sorger et al. (2012)) showed spelling of all letters of the alphabet with differential imagery using rtfMRI-based control, an achievement currently unthinkable with neuroelectric responses.

In addition to the rtfMRI-BCI approach, near-infrared spectroscopy (NIRS) is also a noninvasive technique based on measuring metabolic changes of the brain. Using multiple pairs or channels of light sources and light detectors operating at two or more discrete wavelengths at near-infrared range (700–1,000 nm), cerebral oxygenation and blood flow of particular regions of the cortical surface can be determined. The degree of increase in regional cerebral blood flow (rCBF) exceeds that of the increase in regional cerebral oxygen metabolic rate (rCMRO2), resulting in a decrease in deoxygenated hemoglobin in venous blood during higher oxygen demand. Therefore, an increase in total hemoglobin and oxygenated hemoglobin with a decrease in deoxygenated hemoglobin can be measured in activated brain areas. The recent development of portable systems makes NIRS a promising tool in noninvasive BMI/BCI research (Sitaram et al. 2007). Such a system might be of particular relevance for bedside testing and applying BMI/BCI systems for communication (Birbaumer et al. 2014).

Invasive BMI/BCI

The current research on invasive BMI/BCI mainly steers toward restoration of motor function in patients with quadriplegia to partly overcome their motor impairments (Collinger et al. 2013; Velliste et al. 2008; Hochberg et al. 2006), and less toward restoration of communication in locked-in patients. While invasive BMI/BCI has received the majority of the scientific and media attention, its significance for dealing with clinical problems related to LIS or complete paralysis is minor so far. It is unclear whether invasive BMI/BCI technology provides a reasonable solution with which these patients can communicate.

It is unquestioned that population codes of neural cell assemblies, represented in the firing patterns of its single cells, constitute the substrate for behaviorally relevant information. Whether it is the spiking of cells or the synaptically generated local field potentials (LFP) that encode this information is debatable (see Abeles 1991). Nevertheless, if all population codes of behaviorally relevant cell assemblies are recorded with an implanted electrode array, such invasive BMI/BCI would offer the largest degrees of freedom. Translation of neuronal spiking with linear algorithms recorded with multi-electrode implants in the motor cortex (Nicolelis 2012) or parietal cortex (Velliste et al. 2008) has allowed realistic reconstruction of functional hand and arm movements in 3D-space. So far, the BMI/BCI performance

accuracy of these systems cannot be reached with noninvasive electro- or magnetoencephalography (EEG/MEG) based BMI/BCI systems. However, decoding of two- to three-graded movement dimensions such as reaching and grasping or right-left movements using noninvasive MEG recordings has been demonstrated (Waldert et al. 2008). Hochberg et al. reported on human individuals who received a 100-microelectrode implant placed in their motor cortex and who were able to move and grasp with a robotic arm (Hochberg et al. 2006, 2012). These patients, though, were neither locked-in nor completely paralyzed, and not in need of a BMI/BCI device as this type of control of a robotic arm or computer cursor could be realized by using intact eye or head muscles.

Controlled studies are required that investigate the necessity of an invasive procedure for any therapeutic or assistive application of a BMI/BCI. Risk-benefit ratio is yet to be systematically evaluated. Versatile high-dimensional control of external devices acquired within a few hours or days represents a major advantage of invasive BMI/BCI systems, while their relevance for application in restoration of communication in LIS or complete paralysis remains uncertain.

A series of BMI/BCI studies on human patients with subdurally or epidurally implanted macroelectrodes recording ECoG in presurgically implanted patients with epilepsy (Leuthardt et al. 2004; Hinterberger et al. 2008) showed high classification rates of 70–90 % accuracy in selecting letters from different speller systems using brain oscillations derived from motor-related areas with frequencies up to the high gamma range without extensive training times. Patients used different types of imagery to select or ignore a particular letter or object from a computer menu. These studies are of experimental interest only, because none of these patients needed a BMI/BCI for communication or movement. However, BMI/BCI control is usually better with ECoG than EEG for obvious biophysical reasons. It has to be shown, however, whether invasive BMI/BCI will offer a more reliable and reasonable option for restoration of communication than any of the available noninvasive options.

Current Challenges

Besides missing evidence that any BMI/BCI can be reliably controlled after onset or transition into CLIS, a substantial challenge is the high rate of false positive and false negative classifications during BMI/BCI control. False positive classifications lead to unintended commands that impede the possible use and applicability of BMI/BCI systems. Useful communication (based on simple “yes” or “no” answers) needs at least 70 % correct classification of brain signals over an extended period of sessions (Perelmouter and Birbaumer 2000). The limited reliability of any of the available BCI/BMI systems has important normative implications, e.g., in the context of informed consent or any BCI/BMI-based communication with important consequences for the patient, e.g., medical or legal decisions. Another problem is that the vigilance and attention span of paralyzed individuals is often highly fluctuating.

After failure to communicate with individuals in CLIS using EEG-based BMI/BCI and other measures (e.g., pH-recordings (Wilhelm et al. 2006)), it was tested whether improving the quality and degrees of freedom in the brain signals (e.g., by using single cell firing or LFP after implantation of an electrocorticogram (ECoG)) would allow for better communication. ECoG electrodes were implanted in two individuals diagnosed with an advanced stage of ALS. However, none of these two patients achieved reliable brain communication rates with ECoG-BMIs (Birbaumer 2006).

This essentially negative result of invasive brain recording in CLIS suggests a more fundamental theoretical problem of learning and attention in brain communication with BMI.

Extinction of Thought

A meta-analysis of all reported ALS patients by Kübler and Birbaumer (2008) and a longitudinal study by Silvoni et al. (2013) indicate that no patient in CLIS has ever achieved sufficient communication rates and BMI/BCI performance meeting a 70 % correct threshold for sufficient on-line classification of "yes" or "no" responses. This threshold was tested by using questions with definite answers (e.g., "your name is Anton").

Although individuals in CLIS would benefit the most from direct brain communication, only a few investigations have aimed at finding reasons for the failure to achieve reliable BCI control in this population. It has been hypothesized that losing reinforcement contingencies between behavior and its feedback leads to extinction of goal-directed thinking and voluntary intentions. In complete paralysis, thoughts or motor intentions are not followed by their anticipated consequences. This would result, over a period of time, in extinction of goal-directed thinking itself (Birbaumer 2006; Kübler and Birbaumer 2008). Any attempts to use operant conditioning of the human brain after onset of complete paralysis (e.g., in complete locked-in syndrome (CLIS)) would fail even if afferent input and cognitive processing (attention, memory, imagery) remained intact.

If the voluntary response is only cognitive, such as in covert goal-orientated imagery in the locked-in state, the feedback or reward does not follow a reliable environmental or internal change and consequently extinguishes. Psychophysical studies (Haggard et al. 2002) demonstrate that if the behavioral response is elicited independently of a conscious decision and intention, the conscious awareness of the contingency and the conscious experience of the decision (the 'will') vanish. However, it is conceivable that CLIS patients use internally imagined response-effect contingencies that allow for the maintenance of goal directed thinking.

The hypothesis of extinction of reward-based learning in paralyzed organisms is supported by findings of experiments on curarized rats (Dworkin and Miller 1986). These studies have demonstrated the inability of operant (voluntary) learning to control visceral functions under complete paralysis. As the life-sustaining bodily functions of curarized rats were kept constant in these experiments, the homeostatic effect of the reward (rewarding brain stimulation or avoidance from shock) on body functions and, as a consequence, on learning was absent.

However, Dworkin showed that despite the absence of instrumental learning, classical conditioning of curarized rats was possible (Dworkin 1993). After pairing

tones with aversive stimuli, they learned to control autonomic functions such as blood pressure, vasoconstriction, and heart rate in response to the tones (Dworkin and Dworkin 1995). Following this conceptual framework, Razran, a student of Pavlov, demonstrated classical *semantic* conditioning (Razran 1961). In such a paradigm, words or sentences belonging to different semantic categories are presented as a conditioned stimulus (CS). One specific semantic category (i.e., the thought "no") is followed by an unconditioned stimulus (US), usually a non-painful electric shock. Razran showed semantic conditioning of saliva production to words with positive valence and found evidence for transfer to synonyms, but not to homophonic words. In the same way, he demonstrated generalization to sentences with identical contextual statements or even emotional valence, independent of the constituent words of the sentences (Razran 1949, 1961). Previous studies of cortical correlates of differential semantic classical conditioning have shown an increased amplitude of the evoked brain responses (event-related potentials, ERPs) following the onset of the conditioned stimulus (CS; pseudowords or syllables) predictive of an aversive event (Montoya et al. 1996; Heim and Keil 2006). Following these findings, Birbaumer and his team developed a classical semantic conditioning BMI/BCI allowing online classification of different components of EEG oscillations, ERPs and NIRS signals associated to "yes" or "no"-responses in such a classical semantic conditioning paradigm (Furdea et al. 2012; Ruf et al. 2013; DeMassari et al. 2013b).

Obviously, classical semantic conditioning of autonomic responses or brain responses does not depend on goal-directed motor systems and involves only minimal attentional resources and effort. Thus, classical semantic conditioning may circumvent extinction of volition, goal-directed thinking, effortful selective attention, cognitive control, imagery, and working memory functions during operant learning and, thus, represent a principle to maintain communication in complete paralysis. By implementing a classical semantic conditioning paradigm into a metabolic NIRS-based BMI, a first successful case of communication with a CLIS patient was reported recently (Birbaumer et al. 2014).

A particular challenge is the validation of answers to open questions, as validation often depends on family members and long-term nursing personnel who likely introduce biases toward their own expectations. Frequent repetition of questions that are semantically differently phrased (i.e. "you are in constant pain," instead of "you are NOT in constant pain") might help to control for this problem.

In summary, first studies suggest that classical semantic conditioning might be a possibility to overcome the "silence" after onset of CLIS, particularly when using metabolic brain signals due to the superior learning to control these brain signals. However, replication of these findings in a larger group of CLIS patients is necessary.

Vigilance and Fragmentation of Sleep

Finally, LIS and CLIS caused by destruction or degeneration of the motor system and the connected frontal areas in ALS, or due to brain stem stroke or other brain damage, is usually accompanied by changes in circadian rhythm, sleep pattern, and arousal with alterations of attentional performance (Soekadar et al. 2013).

These changes may at least partially be responsible for failing to establish BMI/BCI communication. While in LIS (locked-in state) with intact eye-control and other states of incomplete paralysis, circadian rhythm is largely preserved, sleep polysomnographic recordings over many nights in one CLIS patient with implanted ECoG-electrodes showed increasing fragmentation of slow wave sleep (SWS), even during day time hours (Soekadar et al. 2013). BMI sessions usually are scheduled during daytime hours, without polysomnographic recordings and without on-line detection of sleep. Fading vigilance during learning of BMI-based communication methods may be an inevitable consequence, because sleep cannot be detected behaviorally by any means in a motionless, eyes-closed, and artificially respirated CLIS patient, except through analysis of EEG signals.

The relationship between vigilance and (possibly any) BMI/BCI performance was also substantiated in several post-hoc analyses of available data recorded in LIS patients, indicating an inverse correlation (ranging from 0.4 to 0.7) between the reduction of P300 amplitudes (assessed during an "auditory odd-ball task" requiring patients to count specific rare auditory stimuli) and BMI/BCI performance based on semantic conditioning across multiple sessions (DeMassari et al. 2013b).

Ethical Dimensions of Brain-Computer Interfaces for Communication

The ethical dimensions of BMI/BCI technology for communication in paralysis can be divided into the following areas: (1) ethical aspects related to advanced directives and the process of informed consent toward the use of assistive technologies and life-sustaining measures, (2) ethical aspects directly related to the use of such technology, and (3) ethical aspects related to the availability and access to such technology.

The issue of informed consent, defined as the process in which participants or legal representatives become fully informed about the risks, potential benefits, and costs of a medical treatment, procedure, or clinical trial, is regulated in most countries (e.g., the Directive 2001/20/EC in the European Union or the Code of Federal Regulations, CFR, Title 21, Part 50.20 in the United States of America). Application of BMI/BCI systems in this regard does not differ from use of any other assistive or supportive technology in patient populations. However, proper discourse over the cost-benefit ratios requires involvement of multiple parties with complementary expertise, particularly to avoid having end-of-life plans that are changed based on false hopes and misinformation. Multiple strategies and guidelines were formulated to assist clinicians and researchers in this process (Haselager et al. 2009).

Current legal systems in most industrialized countries provide the possibility to declare a 'patient will' or 'advanced directive' in case of medical emergencies. The patients' "advanced directive" or "patient will" can include the wish that "artificial" life-preserving medical interventions such as artificial respiration and feeding and similar intensive care measures would be prohibitive and should be avoided. In most cases, however, these patients' wills are signed long before such medical

emergency occurs. The underlying assumption of the signing persons (and these documents) is very often that the circumstances requiring life-preserving measures are associated with a poor quality of life.

In contrast to a large body of studies, the widespread assumption prevails that quality of life in advanced stages of ALS, chronic stroke, and other chronic and untreatable neurological disorders associated with paralysis and dependence of daily assistance or life sustaining measures is poor. The opposite is the case: several longitudinal studies indicate that quality of life in such populations is average and sometimes even above average despite paralysis, artificial respiration, and feeding (Lulé et al. 2013; 2009; Kübler et al. 2005a, 2006, Kübler und Birbaumer 2008). It was found that paralyzed and respirated ALS patients may judge their quality of life as satisfactory and good, while others consider the motionless individual to have a very poor quality of life (Kübler et al. 2005a; Lulé et al. 2009, 2012; Matuz et al. 2010; Pantke and Birbaumer 2012). Despite these results, about 95 % of all individuals diagnosed with ALS "choose" to die before tracheostomy and artificial respiration (Borasio 1996; Neudert et al. 2001). These studies suggest that patients' will-declarations or advanced directives may be invalid at the decisive time points. They may serve as an argument for the medical professions, insurance companies, or family members to shorten anticipated long periods of care for these patients and avoid the financial and social burdens. Patients themselves may follow the social pressure and accept the poor quality-of-life prognosis and ask for hastened death.

The ethical aspects directly related to the use of BMI/BCI technology concern the expected consequences on the quality of life of the users (and their relatives/caregivers), possible risks and side-effects, lack of reliability that might lead to erroneous interpretation of the user's intention (with normative implications for issues such as informed consent or life-changing decisions), and also include other issues like human dignity, mental and bodily integrity, personhood, and communication to the media (Nijboer et al. 2011; Clausen 2011). These aspects are partly subject of dynamic technological advancements, and in part identical to issues raised in the context of the applications of other neurotechnological tools, such as deep brain stimulation (DBS) or cochlea implants.

There is one dimension, however, that becomes increasingly important given that BMI/BCI can be used to diagnose contextual awareness and enable completely paralyzed patients to communicate. In acute locked-in syndrome (LIS), eye-coded communication and evaluation of cognitive and emotional functioning is very limited, because vigilance is fluctuating and eye movements may be inconsistent, very small, and easily exhausted, leading to the provisional diagnosis of CLIS. It has been shown that more than half of the time it is the family and not the physician who first realized that the patient was aware. Recent studies reported that the diagnosis of LIS on average takes over 2.5 months. In some cases, it took 4–6 years before aware and sensitive patients, locked in an immobile body, were recognized as being conscious (Laureys et al. 2005). Once a LIS patient becomes medically stable, and given appropriate medical care, life expectancy increases to several decades. Even if the chances of good motor recovery are very limited, existing eye-controlled computer-based communication technology currently

allows the patient to control his environment, use a word processor coupled to a speech synthesizer, and access the internet (Caligari et al. 2013).

The availability of such assistive technology, including BMI/BCI systems, may force us to disregard death requests formulated in advanced directives or patient wills that were signed long before the present state of a disease. It might urge for the formulation of guidelines and more differentiated courses of action in the case of onset of complete locked-in syndrome (CLIS) and the case that recovery of communication is unsuccessful over a specified period of time.

Knowledge about the possibility of contextual awareness in the unresponsive and recovery of communication despite complete paralysis (though unresolved) requires a broader discourse about the regular application of EEG monitoring and use of BMI/BCI systems in such populations, even if first attempts to restore communication fail.

This raises the issue of availability, access, and proficiency to use such technology within the medical systems. Given the existential dimension and preventable suffering of individuals who are cognitively intact and aware but have no means to express such awareness, a problem of increasing relevance due to demographic developments, e.g., rising incidence of stroke and improved survival rates after traumatic brain injury (TBI), society needs to decide on how it wants to face this reality to avoid that "loosing the capacity for communication means loosing life" (Hohl 1984).

Based on the available studies presented in this chapter dealing with the application of BMI/BCI technology for communication, the following points seem to be of particular relevance:

1. The diagnosis of a progressive disease that might lead to CLIS requires a thorough discussion with the patient and his/her relatives and caregivers about the quality of life for individuals in a state of complete paralysis.
2. BMI/BCI might become a technical option to sustain or restore communication for individuals in CLIS, but more studies are needed that involve such patients. Up until now, no scientifically tested BMI/BCI systems provided reliable communication in CLIS.
3. Given the high rate of misdiagnosed individuals with contextual awareness despite the diagnosis of a vegetative state (VS) (Naci and Owen 2013; Cruse et al. 2011), repeated testing of unresponsive individuals seems advisable. This also applies to patients in CLIS, as their vigilance might be highly fluctuating (Soekadar et al. 2013) or their awareness might be compromised by episodes of minimally conscious state (MCS).

Future Outlook and Conclusions

Since the presence of a patient's awareness significantly impacts multiple ethical dimensions including social, medical, and legal issues related to surrogate decisions on end-of-life care and others, there are an increasing number of people advocating for mandatory additional testing of covert awareness in those diagnosed as

behaviorally unresponsive (Kotchoubey et al. 2013; Cruse et al. 2011). Besides the possibility for repeated attempts to detect task-related changes associated with motor imagery, the ability to employ long-term EEG monitoring would allow quantification of vigilance possibly affected by increased sleep fragmentation and disturbed circadian rhythm (Soekadar et al. 2013).

Innovative paradigms that are particularly promising for communication with complete locked-in syndrome (CLIS) patients based on classical semantic conditioning (DeMassari et al. 2013b) might be particularly useful to detect covert awareness in the behaviorally unresponsive and to restore communication. Application of different approaches ranging from eye-gaze or pupil response-based assistive systems to adequate BMI paradigms based on the combination of different brain signals (e.g., using the combination of NIRS and EEG) might improve the reliability of BMI/BCI systems for communication. In this context, the assessment of the individual's "decision making capacity" might become a relevant aspect, e.g., when involving a patient into meaningful clinical decision-making or legal processes (Peterson et al. 2013).

From a clinical and an ethical perspective, a proper and repeated evaluation and diagnosis of patients' state of consciousness whenever in question, especially in those who are behaviorally unresponsive, seems advisable or even mandatory.

Recent advances in technology have allowed for communication with severely paralyzed individuals (e.g., those suffering from locked-in syndrome or paresis after stroke or brain injury). Multiple clinical studies indicate that these patients may, in fact, have a higher quality of life than otherwise assumed by outsiders, or than they expected themselves before entering a specific state of paralysis. In addition, recent studies have shown that some of those who have previously been perceived as behaviorally unresponsive and in vegetative state were misdiagnosed and consciously aware. While these findings are a consequence of the availability of novel technologies, such as BMI/BCI systems, they raise several ethical questions, for example, the role of advanced directives, which are written long before an individual is in a certain state. In addition, improving reliability and applicability of these tools in completely paralyzed or behaviorally unresponsive patients represents a major scientific and medical challenge. There are many indicators, though, that this challenge can be mastered, given the necessary political will. Particularly, access to these technologies and how they should be used are questions that will require intensified interdisciplinary discourse and interactions between patients, caregivers, physicians, engineers, and scientists, as our ability to sustain, preserve, and enhance human life continually improves.

Acknowledgments We thank Sook-Lei Liew and Birgit Teufel for their help in preparing this manuscript. Ethical Issues in Brain–Computer Interface Research and Systems for Motor Control

45

Donatella Mattia and Guglielmo Tamburrini

Contents

Abstract

BCI (brain-computer interface) systems for motor control process patterns of brain activity and translate them into signals which enable one to replace, restore, or improve impaired motor capabilities. BCI operation involves sustained interactions of the central nervous system with computational and robotic systems that are themselves capable of adaptive behaviors. This fact molds distinctively BCI ethical issues. Indeed, experimental BCI therapies for motor rehabilitation target directly brain areas and raise special informed consent and medical beneficence issues in view of the fact that the functional

implications of brain plasticity are not fully understood and are difficult to predict. Similarly, epistemic limitations concerning the future behaviors of adaptive BCI systems shape ethical reflection on retrospective distribution of responsibilities and liabilities for damages caused by BCI-actuated devices.

Novel ethical issues arise in connection with more distant prospects for BCI enhancement of unimpaired motor capabilities. Ethical policy formation about BCI-enabled enhancements appears to be premature in view of technological lack of imminence. Nevertheless, watchful monitoring of BCI research is presently called for, in order to anticipate prospective ethical tensions between the claims of personal freedom to enhancement and the claims deriving from social justice, fairness, and mental and physical integrity considerations.

On the whole, BCI systems afford unique potential solutions for protecting the autonomy, the action, and even the thinking capabilities of people affected by severe motor impairments. However, trust building between BCI researchers and various groups of stakeholders requires the development of communication strategies which enable one to appreciate the rapid advancements in BCI research without underestimating at the same time the formidable challenges one has to meet before various forms of BCI-enabled communication and motor control become more widely available.

Introduction

A brain-computer interface (BCI) processes brain activity online and identifies patterns of this activity that one uses for a variety of communication and motor control purposes. More recently, BCI systems have been used for brain-monitoring purposes too.

Motor control has been a major focus of BCI research from its very beginning. There, selected patterns of brain activity are processed and translated into signals which enable one to replace, restore, or improve impaired motor capabilities (Millán et al. 2011; Wolpaw and Walpow 2012, see Chaps. 1, 11, 22). For example, BCI-actuated prostheses, robotic manipulators, and wheelchairs may *replace* the functionalities of impaired or lost limbs. By delivering electrical impulses to the muscles of a paralyzed hand, BCI systems enable one to *restore* hand control when normal neuromuscular pathways are disrupted as a consequence of spinal cord injury. And BCI systems have been more recently used to monitor brain activity patterns in the course of poststroke rehabilitation therapies, with the aim of *improving* brain motor control and movement execution.

In addition to these various assistive and rehabilitative applications, one may envision prospective uses of BCI systems in the service of healthy people. BCI prototypes for the general population include systems for attention, emotional state, and mental workload monitoring, photograph or video archive sorting, and game playing. Current limitations of BCI communication channels in the way of

bit-rate transfer suggest that only special categories of healthy users may benefit in the near future from suitable BCI systems for motor control. It has been suggested that astronauts might be one of these categories, insofar as mental teleoperation enables one to govern external semiautomatic manipulators in microgravity working conditions (Millán et al. 2006).

A variety of ethical issues arise in connection with experimental research on BCI systems for motor control and their intended uses in both medical and nonmedical contexts. These issues are not unique to BCI systems: they are closely related to ethical themes emerging in other areas of neuroethics (Clausen 2009), and they are subsumed under standard categories of applied ethics, such as informed consent and respect for persons, medical beneficence, autonomy and liberty, responsibility and liability, distributive justice, and responsible communication of research results (Clausen 2008; Tamburrini 2009). Nevertheless, various distinctive traits of BCI ethics emerge from combinations of the following circumstances:

(i) *Brain-computer mutual adaptation*. BCI operation involves the interaction of two *adaptive* controlling units. These are the central nervous system (CNS) and the computer program which identifies features of brain activity and translates them into control signals.

(ii) *Machine intelligence*. BCI-controlled devices are endowed with varying degrees of intelligence and autonomous action capabilities. This design choice is usually motivated by compelling technological reasons.

(iii) *Potential users*. The groups of potential users who are more likely to take advantage in the near future from BCI systems are formed by persons affected by severe motor impairments: in particular, by those who are left with very limited or no residual capabilities for voluntary movement.

The ensuing reflections on (i)–(iii) prepare the ground for an examination of ethical issues that are shaped by various combinations of these items.

Brain-Computer Mutual Adaptation

Interaction between a BCI system and its user starts from the performance of some *mental task* on the part of the user. During task performance, the user's brain activity is *recorded* and *processed* online in order to *recognize* the presence of features that one *translates* into control signals for some external device. Finally, the user obtains a (perceptual or linguistic) *feedback* about the outcomes of this repeatable interaction cycle.

This closed-loop functional scheme can be multiply realized in ways that are conditional on available kinds of BCI hardware and software, on the invasive or noninvasive character of brain signal recording devices, on the use of synchronous or asynchronous interaction protocols, and on the variety of brain signals that are acquired and processed. The latter include sensorimotor rhythms or P300 event-related potentials (ERPs) among the electrical signals and BOLD (blood oxygen level dependent) responses among the metabolic signals. Additional taxonomies arise on the basis of a variety of informative distinctions, which comprise those

between dependent and independent, active and passive, and hybrid and non-hybrid BCI systems (Wolpaw et al. 2002; Wolpaw and Walpow 2012).

Mutual adaptations between CNS and BCI arise from information exchanges flowing in accordance with the basic functional organization of brain-machine interactions outlined above. These mutual adaptations occur in both preparatory stages and normal operating conditions.

To begin with, one should be careful to note that a central component of a BCI system is a computer program which recognizes some given number of brain activity patterns. For example, in order to set up a BCI system for controlling a robotic wheelchair (Millán et al. 2004), one has to develop a computer program which is capable of recognizing as many brain activity correlates of different mental tasks as one needs to issue a repertoire of basic motor commands, such as “turn left,” “turn right,” “go ahead,” and “stop.” These computational components of BCI systems are usually developed by means of *machine-learning* techniques and protocols (Müller et al. 2008), which crucially involve a *training* phase carried out on a sample of brain activity correlates of mental task performance. Since brain activity patterns vary across different subjects during the performance of the same mental task, this training phase is crucially needed to tune the machine up to its individual user, thereby achieving satisfactory classifications of his or her brain activity patterns.

The need for machine-to-human adaptation by learning may arise during normal operating conditions too, as soon as one observes significantly declining classification performances on the part of the machine. Deteriorating classification performances depend on various factors affecting brain correlates of mental task performance: fatigue, increased familiarity with mental tasks, changes induced by biological clocks, and variable attention levels are notable cases in point.

Initial machine-to-human adaptations are followed by human-to-machine adaptations throughout BCI normal operation. As a matter of fact, an operant conditioning process usually intervenes to change brain activity patterns whenever the user obtains negative feedback information, that is, whenever the user receives notification of discrepancies between expected and actual outcomes of her interaction with the machine. As a result of operant conditioning, brain activity patterns change in ways that have been found to facilitate ensuing machine classifications.

The basic functional organization of BCI interactions is modifiable by taking advantage of additional machine-to-human adaptation processes. The detection of so-called error potentials is a significant case in point. Error potentials are components of ERPs associated to the brain processing of errors, which arise a few hundred milliseconds after presentation of perceptual stimuli that the CNS will recognize as errors (Hoffmann and Falkenstein 2011). A BCI which learns to identify error potentials may undertake a self-correcting action before its human user is able to notify the error to the machine or to issue some correction command by means of the usual BCI communication channel (Buttfield et al. 2006).

Machine Intelligence

In noninvasive BCI systems, the need for some degree of autonomous intelligent action on the part of BCI-actuated devices, such as robotic wheelchairs or manipulators, chiefly arises from current limitations in bit-rate transfer (Wolpaw et al. 2002). In view of these limitations, users are confined to issue commands or convey chunks of information whose coding requires sequences of few bits only. For example, users may instruct a robotic wheelchair to move left or right, but they can hardly plan and control its left or right steering course in a more detailed fashion. Accordingly, one usually delegates lower-level control of left or right commands to the robotic wheelchair. Similarly, BCI-actuated robotic systems are entrusted with the job of meeting important deadlines that otherwise would be missed on account of the BCI bit-rate bottleneck. A pertinent example is the timely avoidance of unexpected obstacles on the trajectory of a robotic wheelchair. More in general, the use of BCI-actuated robots involves a division of labor between man and machine in the way of intelligent control: the user selects higher-level commands, and the machine, which is thereby granted some degree of autonomy, plans and carries out lower-level subtasks (Millán et al. 2004; Galán et al. 2008).

Classes of Potential Users

In view of the bit-rate bottleneck, current BCI systems – and especially the more widely used noninvasive systems – compare unfavorably with many alternative assistive technologies that are available to people who are able to make a variety of voluntary movements. For this reason, BCIs afford viable and often unique solutions for restricted groups of people only, that is, for those who are left with no or very limited movement capabilities. Indeed, early prototypes of BCI systems were conceived and developed for the benefit of people affected by the *classical* locked-in syndrome (LIS), which results in the complete paralysis of nearly all voluntary muscles except for eye moving and blinking (Farwell and Donchin 1988). One must be careful to emphasize, however, that effective use of BCI systems has not been demonstrated yet in the condition of *complete* LIS, that is, in the case of people who cannot perform any voluntary movement at all (Hochberg and Anderson 2012).

Consider now the impact on familiar ethical issues which derive from mutual man–machine adaptations in the BCI context, from the intelligence embedded into BCI-actuated devices, and from the special needs of users who are more likely to take advantage from BCI-enabled replacement of motor functions.

Informed Consent and Respect for Persons

Along with healthy participants, research trials on BCI-enabled replacement of motor functions may enrol people who have lost most of their abilities to

communicate and act. Clearly, these research trials are unlikely to bring personal advantages to disabled participants. Nevertheless, disabled participants and their families may come to view a BCI research trial as a unique and last resort to overcome excruciating communication and action barriers. These unrealistic expectations might be so compelling in the dramatic human condition of severely paralyzed persons that they prevent a proper appreciation of the facts one must know before participating in BCI experimentation (Haselager et al. 2009; Clausen 2011; Vlek et al. 2012). Accordingly, specific information aimed at anticipating and mitigating similar psychological reactions must be included in setting up informed consent questionnaires and protocols for BCI experimentation. In particular, one must provide clear and detailed information about the phenomenon of BCI illiteracy, that is, the incapability to operate a BCI, which is estimated to affect 15–30 % of potential users, and for which effective remedies are still to be found (Vidaurre and Blankertz 2010); about psychological risks of depression which may derive from retracting BCI use at the end of time-limited studies (Schneider et al. 2012); and about discomfort and complications in the care of disabled participants which may derive from prolonged operation and maintenance of BCI systems (Wolpaw and Walpow 2012, see Chap. 20).

It was pointed out above that the interaction of two adaptive controllers is crucially involved in BCI training and operation. As one shall see later on, distinctive risks arise in connection with unsatisfactory outcomes of machine-to-human adaptations. But ethically more significant concerns arise in connection with potentially deleterious changes in the CNS resulting from human-to-machine adaptations. Consider, from this perspective, BCI-enabled replacement of user motor functions. There, psychological rewards and punishments deriving from the observation of BCI interaction outcomes enable the CNS to learn and modify its activity so as to facilitate BCI actuation of user intents. Learning occurring in the BCI context is a source of brain plasticity (Wolpaw and Walpow 2012, see Chap. 13). Accordingly, as the overall functional implications of brain plasticity are not fully understood and difficult to predict, one cannot rule out generic risks of detrimental effects on states of mind and behaviors of BCI intensive users (Schneider et al. 2012). Ethically motivated safeguards that are similar to those adopted in connection with psychoactive medications (Merkel et al. 2007; Clausen 2009) or deep brain stimulation (DBS) devices (Clausen 2010) must be put in place to deal with similar risks. Neurologists, psychologists, and other medical personnel involved in BCI research and assistance to BCI users carry the moral duty of constant monitoring for timely detection of adverse consequences and risk assessment update. And every BCI candidate user must be properly informed of potentially detrimental effects of BCI-induced brain plasticity (Dobkin 2007).

Some BCI-based rehabilitation therapies for improving motor functions *target directly* brain areas, with the principal aim of modifying their structure and functions (Shih et al. 2012). This intended use of BCI systems differs from the use that one generally makes of these systems in order to replace lost motor functions. Indeed, BCI systems for controlling robotic wheelchairs do not aim directly at

changing brain structure: intervening modifications of this sort, if any, are a side effect of intensive BCI operation.

Various rehabilitation strategies have been made available to foster BCI-induced changes in the CNS. One strategy for poststroke motor rehabilitation, for example, involves a BCI system monitoring damaged motor areas of the brain which normally control movements that are impaired after brain injury. The BCI system provides appropriate feedback according to whether activation patterns in the targeted brain areas come closer to normal or not (Grosse-Wentrup et al. 2011; Pichiorri et al. 2011; Daly and Sitaram 2012; Mattia et al. 2012; Várkuti et al. 2013). One may use *hybrid* BCI systems for similar purposes (Bermudez et al. 2013): BMCI systems (with the letter "M" in the acronym standing for *muscle*) combine the analysis of brain signals and electromyographic signals to stimulate increasingly correct activity patterns in both brain and muscles.

Ethical concerns about BCI systems directly fostering brain plasticity arise, at a general level, from awareness of limited etiological understanding of deleterious effects, if any, of these interventions. This epistemic predicament calls for sustained monitoring of BCI-based therapies directly targeting the brain. However, no guidelines have been developed yet for risk management and sharing of data about these experimental therapies. Protection of the mental and physical integrity of patients provides a major ethical motivation for setting up research and task forces which aim at filling this gap. Candidate participants in these experimental therapies must be specifically informed of the fact that modifications in brain areas are a direct objective of these interventions rather than side effects resulting from intensive use of BCI systems.

More straightforward ethical recommendations concern informed consent about the use of *invasive* versus *noninvasive* BCI systems. Operation of invasive BCI systems requires the implant of electrodes in the cortex (Velliste et al. 2008; Hochberg et al. 2012; Collinger et al. 2013) or the deployment of apparatuses for electrocorticography (ECoG) or intracranial electroencephalography (iEEG) on the exposed brain surface (Moran 2010). Compared to noninvasive BCIs, invasive ones achieve better spatial signal resolution and signal-to-noise ratio leading to improved control of peripheral devices. Among the noninvasive systems, those relying on the EEG as a recording method afford better performances in terms of signal temporal resolution, cost, and practicality of use. Potential users of BCI systems must be informed of comparative advantages and disadvantages of invasive and noninvasive systems, including relevant facts about characteristic risks of invasive systems in connection with implant stability, reversibility, and infection. Interestingly, empirical data from interviews administered to people affected by amyotrophic lateral sclerosis (ALS) suggest a definite preference for noninvasive systems, notwithstanding the functional advantages of invasive BCIs which derive from better spatial resolution and signal-to-noise ratio, and the corresponding disadvantages of noninvasive systems in the way of slower operation and more error-prone control (Birbaumer 2006).

Beneficence, Justice, and Autonomy

International declarations on human rights furnish a very general ethical framework for addressing a variety of specific beneficence issues in bioethics. These documents notably include the United Nations Universal Declaration of Human Rights (United Nations 1948) and the more recent Charter of Fundamental Rights of the European Union (European Union 2000). A selective examination of these documents – let alone an examination of international treaties and conventions that are more specifically concerned with health-care rights – sheds some light on the operational content that BCI research and systems may bring to human rights promotion and protection. It is worth considering, from this vantage point, the potential contribution of BCI research and systems to the promotion and protection of human dignity.

Article 1 of the UN Declaration asserts that "All human beings are born free and equal in dignity and rights." And Article 1 of the EU Charter asserts that "Human dignity is inviolable. It must be respected and protected." Arguably, BCI systems for replacing impaired motor functions of severely paralyzed persons afford practical implementations of these principles via the conceptual intermediary of the notion of human agency. A human agent is an entity capable of performing a wide repertoire of actions guided by desires, intentions, and beliefs about the world. The vulnerability of human agency as such is dramatically underscored by the condition of people affected by LIS: almost completely lost action capabilities come there with the persisting mental capability to conceive intentions to act. The protection of human agency, which is compromised by LIS, plays a central role in major philosophical views of human dignity. According to Kantian views of dignity, for example, the inherent worth of a human being is ultimately grounded in the capability to act as *homo noumenon*, that is, in the capability to endorse rationally the moral maxims of practical reason and to conform one's own actions to those maxims (Rothaar 2010). And according to neo-Aristotelian views of dignity, the more direct way to realize a dignified human life is to develop and exercise human capabilities for practical deliberation, control over one's own environment, and engagement into social activities (Nussbaum 2006, pp. 77–78 and p. 161). Clearly, both conceptions of human dignity afford moral motivations for specific deeds which aim at protecting the action capabilities of people affected by severe motor disabilities. And these positive actions can be supported by a wide variety of BCI technological platforms, such as those for environmental control, typing, computer access and internet surfing, computer games, virtual drawing, and painting (Millán et al. 2011).

Consider now Article 26 of the EU Charter of Fundamental Rights: "The Union recognizes and respects the right of persons with disabilities to benefit from measures designed to ensure their independence, social and occupational integration and participation in the life of the community." There are different approaches to filling the gap between this general statement and positive actions that are inspired to it. In addition to shared views and political agreement about societal duties toward groups of disabled people, a crucial factor concerns the identification

of the more effective ways to use available resources. Thus, for example, technological research aimed at promoting the rights of disabled persons is encouraged with the crucial proviso of giving priority to the development of technologies at affordable costs (United Nations 2006, see in particular article 4, paragraphs f and g). Accordingly, scientists in the BCI community ought to pay attention to distributive justice concerns in their research work and to look for cost-effective BCI systems and technologies.

BCI systems might even come to play a role in the protection of persons and personhood as such. It was pointed out above that a successful demonstration of BCI use in the complete LIS condition is still missing. This learning inability may depend on a generalized decline of attention, perception, and thinking capabilities which is hypothesized to take over after the onset of complete LIS. According to an alternative explanation, however, sustained preservation of purposive thinking requires psychological reinforcements that occur only if the actual consequences of intended actions are verified. In the complete LIS condition, this reinforcement is occasionally forthcoming through the intermediary of caretakers who happen to fulfil the patient's current desire. Without reinforcement, purposive thinking fades away, and with it goes the capability to learn and operate a BCI. If this alternative explanation turns out to be correct, then one may prevent the extinction of goal-oriented thinking by teaching one how to operate a BCI before the onset of complete LIS (Birbaumer 2006). Accordingly, teaching a person in a state of incomplete or classical LIS how to use a BCI would serve the morally praiseworthy purpose of protecting personhood, to the extent that goal-oriented thinking is a central feature of a person.

Responsibility and Liability

In BCI systems for motor control, selected patterns of brain activity are recognized and translated into signals which enable one to replace, restore, or improve impaired motor capabilities. Thus, the proper functioning of BCI systems crucially requires reliable classifications of brain activity patterns. It was pointed out above that machine-learning methods are usually deployed to develop, on the basis of a variety of training techniques and data, computer programs which classify brain activity patterns. Various estimates of the reliability of learned classification rules can be worked out on both theoretical and experimental grounds. It is well known, however, that each of these estimates involves distinctive background assumptions about the significance of training data or the stability of the stochastic phenomena one is dealing with. Unfortunately, these background assumptions are difficult to buttress when the classification of brain activity patterns is at stake: increased familiarity with mental tasks, in addition to mental fatigue, mental changes induced by biological clocks, variable attention levels, and BCI system setup (such as the variable positioning of the EEG cap across training or normal operating sessions), is known to affect the stability of recorded brain signals. Briefly, the reliability of learned classification rules depends on boundary conditions on brain processing

that are difficult to isolate and control, insofar as task execution history, current mental context, and technical setup procedures concur to jeopardize the stability of recorded brain signals (Santoro et al. 2008). Discrepancies between user intents and actual robotic navigation trajectories may occur in BCI contexts of use even when user intents are correctly identified. These additional disagreements arise in view of uncertainties and predictive limitations which generally concern the behavior of robotic systems, such as robotic sensitivity to small perturbations of initial conditions or sensor noise piling up in series of sensory readings (Nehmzow 2006).

There are ethically relevant issues arising from known epistemic limitations about the behaviors of brain-actuated robots. The retrospective distribution of responsibilities and liabilities for damages caused by BCI-actuated robots is a case in point, insofar as programmers, manufacturers, and users are not in the position to predict exactly and certify what these robots will actually do in their intended operational environments (Tamburrini 2009; Clausen 2011). For example, how are responsibilities and liabilities sensibly distributed if a BCI-actuated robotic wheelchair rolled down a staircase due to its incorrect interpretation of user intents or when a robotic arm responding to a glass-of-water request hits another person standing in the room?

Programmers, manufacturers, and users who failed to predict some damaging event resulting from misclassification of user's intents, perceptual failures, or environmental perturbations cannot be held morally blameworthy, provided that they properly attended, in their different capacities, to every reasonable BCI design, implementation, testing, and operational issue. Nevertheless, even in the absence of moral responsibilities deriving from negligence or malevolent intentions, damaging events give rise to liabilities and objective responsibilities which require proper distribution.

In developing liability policies for brain-actuated robots, one may rely on a large body of legal norms and casuistry concerning liabilities for the use of machinery in general. One should be careful to note, however, that BCI-actuated systems stand out from machines of many other sorts, insofar as the symbol-processing, learning, reasoning, and action planning capabilities that BCI systems share to some extent with human beings and other biological systems are special sources of behavioral unpredictability in principle or in practice.

This positive analogy between the unpredictability of BCI systems and of biological systems suggests that the inability of BCI users to predict exactly and control the behavior of brain-actuated robots is meaningfully related to the inability of dog owners to curb their pets in every possible circumstance, to the inability of employers to predict exactly and control the behavior of their employees, and even to the inability of parents to predict and control the behavior of their children. Parents are nevertheless held to be vicariously liable for many kinds of damaging events caused by their children, just as pet owners are liable for damages caused by their pets, and employers are liable for certain types of damages caused by their employees. Accordingly, users should be held liable for damaging events resulting from unpredictable behaviors of their BCI systems. However, the suggestion of extending to BCI-actuated robots policies regulating liability ascription for

damages caused by unpredictable behaviors of human beings and other biological systems is not immune from ethically motivated criticism. Indeed, a liability policy of this kind may introduce discriminations in the access to assistive technologies between those who can and those who cannot afford the cost of insurance and compensations for damages caused by BCI-actuated devices.

Alternatively, one might shift the burden of economic compensations entirely on BCI manufacturers. In view of their expected profits, producers of goods are often held liable for damaging events that are difficult to predict and control. This liability ascription policy is aptly summarized in the Roman juridical tradition by means of the formula *ubi commoda, ibi incommoda*. However, ethically motivated criticism can be levelled against this alternative suggestion too. Indeed, the risk of high compensation costs may discourage investments in R&D toward the development of marketable BCI systems, with the effect of diverting resources that are much needed to start a pioneering BCI industry. As a consequence, tensions are likely to arise between a liability policy charging compensation costs on BCI producers, the demands of beneficence in bioethics, and consequentialist evaluations of societal benefits that are expected to flow from BCI technological innovation.

These various observations suggest that a complex governance framework, allowing for the socialization of risks associated to this innovative technology, is needed to address properly BCI liability problems. Since BCI technological risk comes with beneficial opportunities for groups of disabled people, in addition to longer-term benefits in the way of technological innovation for society at large, one might appropriately distribute insurance and compensation costs on a variety of stakeholder groups and governmental agencies. Similarly, the problem of identifying criteria for acceptable risk should be addressed within this complex governance framework.

Liberty

Astronauts, it was noted above, are a professional group of healthy users who might take advantage of BCI-actuated robots in view of microgravity conditions hindering their movements. In a more distant future, BCI systems for motor control might prove useful to enhance or extend the motor capabilities of wider groups of healthy people. These envisaged developments raise novel ethical issues, notably regarding the personal freedom to enhance one's own mental and physical capabilities vis-á-vis ethical concerns about mental and physical integrity, justice, and fair social opportunities. These ethical issues are quite novel. They are not equally pressing, however, according to any ethical triage which takes technological imminence in due account (Farah 2002; Tamburrini 2009; Clausen 2011). For this reason, attending now to ethically motivated norms and recommendations about envisioned BCI-enabled motor enhancements appears to be a premature move. Watchful ethical monitoring is presently more appropriate, so as to anticipate and issue early warnings about novel ethical issues, if any, arising from BCI research in this area (Lucivero and Tamburrini 2008). In particular, ethical monitoring is

needed to detect possible tensions between justice and equality on the one hand and personal freedom to use one's own economic resources to get BCI motor enhancement and extension on the other hand; to anticipate emerging pressures to get BCI motor enhancements in view of new job opportunities; and to understand how BCI motor enhancements might come to affect one's own personality, social relationships, and relationships with the natural environment at large.

Responsible Communication of BCI Research

In a democratic society, citizens and special groups of stakeholders responsibly participating in public affairs have to make up their minds about the uses of novel technologies and their coherence with given moral values and aspirations. On the basis of reflective and deliberative processes, individuals may form moral judgments and contribute to develop societal orientations or, more stringently, moral and legal norms about novel technologies. These processes are realistically bound to depend on a division of epistemic labor between ordinary citizens and experts, insofar as one cannot expect that ordinary citizens collect from scratch the background scientific and technological information which is needed to analyze and weigh viable alternatives (Kitcher 2011). Moral responsibilities are distributed accordingly. Citizens carry the moral responsibility to reduce their ignorance about scientific and technological matters which may threaten goals and aspirations that they value most; experts carry the moral responsibility of supplying what is, to their best knowledge, correct and comprehensive specialized information. There are, however, many ways in which experts intentionally or inadvertently produce misinformation about scientific and technological matters (Proctor 2008). Identifying and offsetting the underlying mechanisms is an ethically significant undertaking.

In the BCI context, public statements of researchers about their research goals and activities may become a powerful source of misinformation, insofar as disproportionate technological and therapeutic expectations are generated and amplified at the hands of both media reporting and individual psychological responses (Clausen 2008; Haselager et al. 2009). One might be able to countervail some of these undesirable outcomes of scientific communication by paying due attention to the distinction between the *general framework* of a research program and the series of detailed models, technologies, and systems that a research program brings progressively into being during its life course (Laudan 1978; Godfrey-Smith 2003). The general framework of a research program is put together by identifying basic assumptions about entities and processes in some domain of inquiry, theoretical ideas, and techniques which are heuristically identified as appropriate means to investigate phenomena there, in addition to overall research goals one hopes to attain in the long run. Clearly, the overall goals and promises of a general framework play significant motivating roles in scientific work and may suggest fruitful lines of inquiry, even when these promises cannot be attained without making substantial and unforeseeable progress with respect to currently available models and techniques.

In making public statements about their work, scientists cannot count on the shared background of tacit knowledge which shapes communication styles within their own scientific communities. Accordingly, the ethically praiseworthy goal of furnishing correct and accessible information to the general public raises the formidable challenge of adapting professional communication styles of scientists to the needs of broader audiences of nonspecialists. In particular, scientists should mark clearly up long-term or visionary goals of a research program, setting them apart from tangible results that have been actually achieved. Ethical motivations for carefully drawing these distinctions have emerged in connection with several developments of BCI research. In communicating the research goal of making a variety of BCI technologies and systems available to people affected by LIS, one ought to emphasize problems of BCI system reliability, cognitive decline in LIS patients, the incidence of BCI illiteracy, and the generalizability to clinical contexts of results obtained in research trials involving healthy subjects only. Moreover, one must specify BCI costs and benefits with respect to alternative communication methods for persons who retain some communication capabilities, say, by moving their eyes or eyelids.

The need for responsible communication strategies emerges even more evidently in connection with the suggestion of using BCI for communicating with and promoting the autonomy of people affected by disorders of consciousness. Similar suggestions were advanced in the wake of pioneering studies on communication protocols with persons diagnosed to be in a vegetative state: a limited number of these persons were able to answer autobiographical questions on the basis of a communication protocol involving the performance of a mental task and the analysis of its brain correlates (Owen et al. 2006; Monti et al. 2010). Extensions of this communication protocol were envisaged for the purpose of allowing subjective symptom reporting, informed consent, and other exchanges of information aiming at medical beneficence and autonomy protection. One should be careful to note, however, that assessing whether persons affected by disorders of consciousness still possess the required varieties and degrees of consciousness is a scientifically formidable and empirically elusive problem. In these circumstances, one ought to adopt an extremely cautious attitude in communicating the results of these studies and their possible developments to psychologically vulnerable families of people affected by disorders of consciousness (Tamburrini and Mattia 2011). More in general, trust building between BCI researchers and various groups of interested parties requires the development of suitable communication strategies which enable one to appreciate the rapid progresses made by BCI research without underestimating the formidable scientific and medical challenges that have to be met in the future before various forms of BCI-enabled communication and motor control become more widely available.

Attention Deficit Hyperactivity Disorder: Improving Performance Through Brain–Computer Interface

46

Imre Bárd and Ilina Singh

Contents

Abstract

Novel neurotechnologies, such as brain-computer interfaces (BCI), are generating significant scientific and popular interest. A certain BCI technology, neurofeedback (NF), is increasingly used for managing the symptoms of many conditions, most notably attention deficit hyperactivity disorder (ADHD). Although growing evidence suggests that the method is promising, there is no consensus in the scientific literature about its efficacy, and different sources offer contradictory evaluations. Although neurofeedback has received comparatively little scholarly attention from ethicists, it presents numerous dilemmas that warrant consideration. While the

method is already widely used and its acceptability can be expected to grow, the precise mechanism of action and possible adverse effects of neurofeedback are poorly understood at present. The current regulatory landscape of neurofeedback devices seems inadequate, and in particular, the growing commercialization of BCIs and lack of oversight over EEG-based toys and games present a challenge for neuroethical analysis. After a brief discussion of ADHD, and the emergence of neurofeedback, this chapter provides an overview of assessments of NF's efficacy and a brief survey of some of the ethical and social aspects of the method for pediatric ADHD. The questions covered include adverse effects, regulation, responsible communication, identity considerations, and the enhancement use of BCIs.

Introduction

Novel neurotechnologies, such as brain-computer interfaces (BCIs) and brain stimulation methods, are generating a lot of scientific research and increased media interest (Erp et al. 2012; Kennedy 2011). The ethical and social issues raised by some of these developments are continuously being addressed (Clausen 2008, 2009); however, questions surrounding the use of noninvasive devices, and specifically noninvasive BCIs, have received comparatively less scholarly attention. Unlike invasive BCI technologies that require complex medical interventions, such as neurosurgery, noninvasive devices are relatively easily accessible and can often be used by individuals without expert support. A medical diagnosis is not necessary for purchase or use of these devices, and they can easily become available for both medical and nonmedical purposes.

The use of a certain BCI technology, EEG-based biofeedback, also known as neurofeedback, is growing rapidly as a treatment for various conditions, including attention deficit hyperactivity disorder (ADHD), anxiety, depression and epilepsy (Birbaumer et al. 2009; Budzynski et al. 2009). Recently, some companies have brought neurofeedback software and equipment to the commercial market, which are advertised as improving the symptoms of ADHD, and numerous toys and video games are hitting the shelves that use largely the same technology.

This chapter will give an overview of the use of neurofeedback BCIs for ADHD and address some of the neuroethics questions associated with this practice. The first section will introduce relevant facts about ADHD, followed by an explanation of neurofeedback BCI and its development, how it is practiced, and the current scientific status of the method. The last section will suggest some of the key elements of an ethical framework for use of BCIs for ADHD, using neurofeedback as a current case to think with.

Attention Deficit Hyperactivity Disorder

Attention deficit hyperactivity disorder (ADHD) is among the most commonly diagnosed childhood psychiatric conditions worldwide. Its core symptoms are

hyperactivity, impulsiveness, and inattention, which give rise to three subtypes of ADHD: the predominantly inattentive, the predominantly hyperactive-impulsive, and the combined types. Affected children can have significant difficulties in coping with daily demands at home and in school and may experience stigmatization and exclusion (Singh 2012).

Currently, there are no reliable biomarkers or neuropsychological tests for ADHD; its diagnosis is therefore based on a careful examination of medical history to rule out other possible conditions and, most importantly, on behavior rating scales completed by parents and teachers to assess the nature and degree of symptomatology. The fact that diagnosis relies heavily on subjective appraisals of perceived behavior highlights the importance of social factors for the ways in which the condition is understood. Whatever is considered to be an "impairment" is also contingent upon cultural notions of what constitutes proper childhood behavior, pressures to succeed, and the broader social and educational context in which childhood behaviors are situated (Gualtieri and Johnson 2005).

Diagnostic manuals, such as the Diagnostic and Statistical Manual of Mental Disorders (DSM), consider the diagnosis of ADHD to be categorical and binary – one either has it, or not. However, it is difficult to sharply distinguish normal and pathological symptoms, and recently, there have been calls to move towards spectrum-based approaches in the classification of mental disorders, which may be more appropriate in the case of ADHD as well (Singh 2008; Swanson et al. 2009; Marcus and Barry 2011).

The prevalence rate of ADHD is somewhat difficult to ascertain because numbers vary widely depending on measurement methodology, the sampled population, geographic location, and the diagnostic criteria used. According to one estimate the worldwide prevalence of ADHD is approximately 5 % (Polanczyk et al. 2007), while the CDC reports that in the United States 9.5 % of children aged 4–17 years have ADHD (CDC 2010). Furthermore, the diagnosis of the condition seems to be on the rise, with a reported 66 % increase in the US between 2000 and 2010 (Garfield et al. 2012).

Psychostimulant drugs are the most common form of treatment for ADHD. Their use dates back to the 1930s, and the most commonly used drug, methylphenidate (Ritalin), has been on the market since 1955 (Singh 2002a). The use of stimulants has been increasing steadily over the past decades, and it is estimated to be at 3.5 % overall among children and adolescents in the USA. Prescription stimulant use is highest among 6–12-year-olds, at 5.1 %, while use among adolescents is growing at the fastest rate and is also around 5 %. Boys are three times more likely to receive a diagnosis of ADHD than girls (Zuvekas and Vitiello 2012).

The effectiveness of psychostimulant medications has been established by numerous clinical trials; however, the NIMH-funded Multimodal Treatment Assessment Study (MTA) found that although drug treatment is associated with short-term benefits, these effects dissipate over time. Even the best available treatment, a carefully managed combination of behavioral interventions and psychostimulants, which is the optimal treatment recommended by the American Academy of Pediatrics (American Academy of Pediatrics 2011), provided inadequate benefit in close to

one third of the participants (Molina et al. 2009; Swanson et al. 2001). Furthermore, at follow-ups both at 6 and 8 years, there were almost no significant differences between randomized groups receiving psychostimulant, behavioral, or combined therapy for 14 months. However, with the exception of two variables (the Multidimensional Anxiety Scale for Children anxiety and driving accidents/citations), all treated groups scored significantly lower than the normative control group. Measured variables included behavioral ratings, academic achievement, and overall functioning assessed by the Columbia Impairment Rating Scale. Based on the MTA's findings, children with the least severe initial presentation of ADHD and those with sociodemographic advantage who respond best to any treatment have the best prognosis (Jensen et al. 2007; Molina et al. 2009).

Both the clinical reality of the ADHD diagnosis and the use of psychostimulant drugs in children are the subjects of a heated, ongoing debate, which takes place in the popular press as well as in academic journals. While some critics dismiss ADHD as inappropriate medicalization of normal childhood behavior, others advance more nuanced critiques that do not question the reality of the diagnosis entirely but articulate concerns about overdiagnosis and the wider social dimensions of children's behavior (see Singh 2008 for an overview).

Any intervention to manage ADHD has to be viewed against this complex background. ADHD diagnosis is, at best, an ambiguous medical label that captures a wide range of individuals whose level of impairment can differ significantly. Moreover, stimulant drug treatments have been shown to be effective both in individuals diagnosed with ADHD and in individuals who do not meet criteria for ADHD. This contributes a further opacity to the management of ADHD because the distinction between "treatment" of impairing symptoms and "enhancement" of cognitive capacities can be particularly subtle. Therefore, this chapter will discuss BCIs both as a treatment for ADHD and as an enhancement strategy for individuals who wish to improve their attentional capacities.

What Are BCIs?

Brain-computer interfaces (BCIs) translate readings of the electrical activity of the brain into commands that can be interpreted by computers. In essence, this allows users to operate software, devices, or prosthetics with nothing but their brain states or "thoughts." BCIs can be grouped into two categories. Invasive devices require a neurosurgical intervention to place electrodes on the surface of the brain or to implant them inside the brain. Noninvasive BCIs employ sensors, which are placed on the surface of the scalp to record electroencephalographic (EEG) signals. The primary medical application of BCIs is within the field of assistive technologies for patients with locked-in syndrome and other disabilities, where the method is used to restore lost functionality, such as vision, speech, or control over prosthetics or a wheelchair (Berger et al. 2008).

Irrespective of the level of invasiveness, there are two different approaches to BCIs, which can be distinguished, on the basis of which party is doing most of the

learning: the brain or the computer, although most technologies employ both to some extent. In the *machine learning* approach, sophisticated learning algorithms adapt to the individual user's neural activity through a process of calibration as the subject performs certain tasks, such as imagining body movements. In the *biofeedback* approach, subjects learn to produce certain desired brain states with the help of visual and auditory feedback about their real-time neural activity (Dornhege et al. 2007). Beyond assistive technologies, noninvasive BCIs are increasingly used for a wide range of purposes, including coma detection, meditation training, computer usability research, alternative therapies, performance enhancement, and gaming (Desney and Nijholt 2010).

Most of the research on BCIs to date has been conducted with EEG-based devices. Although there is emerging research about fMRI neurofeedback for ADHD, this technology is still highly experimental (http://public.ukcrn.org.uk/search/StudyDetail.aspx?StudyID=12668). In the future, hybrid devices might appear that combine measurements of various physiological responses, such as electrodermal activity or heart rate, with BCIs.

Because it is the most widely used and studied method, the rest of the chapter will focus on the use of EEG neurofeedback for pediatric ADHD. While the method can look back at a history of several decades, the precise mechanisms of action are still poorly understood.

Neurofeedback

A Brief History of Neurofeedback

At the end of the eighteenth century, the work of Luigi Galvani and Giovanni Aldini introduced the idea of electricity as the agent of peripheral nerve function. This was a revolutionary discovery and in a way it also signaled the start of psychiatry's lasting relationship with the electrical properties of the brain (Ochs 2004). About 100 years later, in 1875, Richard Caton conducted the first electrophysiological recordings of the central nervous systems of animals. Caton was interested in cortical localization, and he postulated that there must be some kind of relationship between the weak currents he had measured and specific brain functions. His work was mostly forgotten until 1929, when Hans Berger, the inventor of the modern EEG, acknowledged Caton's essential role in researching the electrical activity of the brain (Finger 1994).

Berger was the first to record brain waves on paper thus creating the electroencephalogram. Through his work on humans Berger found that the EEG consisted of certain rhythms of which he identified two distinct waves, alpha and beta, and he also postulated that the EEG could be used to detect clinical pathologies (Borck 2005). Throughout the 1930s, the EEG quickly became associated with the promise of deciphering the language of the brain as it gives rise to the mind, and its visual representation, the lines of ink on paper came to be seen as the bridge between biological processes and mental life.

The early history of the EEG intersects with the early history of ADHD. In 1937, Charles Bradley conducted the first trial of a psychostimulant drug, Benzedrine, for the treatment of "behavior problem children" (Bradley 1937). This was a broad category at the time, and it included children who would likely be classed as ADHD today (Singh 2002b). A year later, Bradley, along with Herbert Jasper and Philip Solomon, conducted the first EEG examinations of behavior problem children (Jasper et al. 1938). In this and in subsequent experiments (Lindsley and Cutts 1940), they found an increased rate of slow waves compared to normal controls. However, it is important to note that at the time it was difficult to interpret EEG measurements because there were no normative databases available to compare findings to, and advanced methods for quantifying EEG data did not yet exist. The 1960s brought a number of significant breakthroughs. First, the advent of sophisticated computers led to the emergence of quantitative EEG (qEEG), which gradually enabled more and more features of EEG data to be analyzed, such as frequency, amplitude, morphology, and symmetry (Cantor 1999). In addition, researchers began to establish normative databases that allowed individual measurements to be compared to a representative pool of data (Thatcher and Lubar 2009).

The notion of neurofeedback is predicated on the idea of operant conditioning developed by the father of behaviorism Burrhus Frederic Skinner in the 1930s. It is a form learning where the occurrence of a certain behavioral response is reinforced or extinguished through rewards or punishments (Skinner 1938, 1963). With the emergence of cybernetics, the notion of feedback gained central importance in understanding biological organisms. In neurofeedback, the ideas of the operant conditioning of behavior and feedback in self-regulation were brought together (Kropotov 2009). Thus, neurofeedback is "an operant conditioning procedure whereby an individual modifies the amplitude, frequency, or coherency of the electrophysiological dynamics of his/her own brain" (Thatcher 1999, p. 29). Dr. Joe Kamiya was the first to investigate whether there was any correlation between 1st person subjective experience and certain EEG patterns, namely, bursts of alpha (Kamiya 1968). He also thought to connect an EEG to a machine that sounded a tone whenever subjects produced alpha bursts (Nowlis and Kamiya 1970). He found that such bursts were associated with subtle cues and that through introspection and feedback of their own brain states participants could learn to control alpha consciously. Barry Sterman used an operant conditioning paradigm and trained cats to increase a certain band of the beta wave in the 12–15 Hz range known as the sensorimotor rhythm (SMR), which is associated with immobility (Sterman et al. 1969). It was later discovered accidentally in a NASA study that this training had made the cats highly seizure resistant. Subsequently, this discovery opened the prospect for medical applications of the method in the treatment of epilepsy. These findings generated a lot of research interest and by the early 1970s led to the birth of the discipline of biofeedback, which was also strongly supported in the US during the Vietnam War to produce methods of performance enhancement, especially under elevated stress (Budzynski 1999).

Drawing on successes in the suppression of seizures, Lubar and colleagues hypothesized that training SMR could be used effectively for the reduction of

hyperkinetic symptoms in children and they produced impressive results (Lubar and Shouse 1976; Shouse and Lubar 1979). By this time, stimulant medications were available treatments for hyperkinetic children, and the higher rate of slow waves characteristic of these children has been used as a predictor of positive response to stimulant drugs (Satterfield et al. 1973). As more and more evidence showed that children with ADHD showed cortical slowing in frontal regions, Lubar and Lubar performed the first experiment using a beta enhancement/theta suppression paradigm, which became the basis of most subsequent neurofeedback procedures for ADHD (Lubar and Lubar 1984).

After initial successes and great expectations, the field of neurofeedback suffered a critical setback and fell into disrepute, the reasons for which are still disputed. The method gradually became associated with unrealistic claims related to consciousness expansion, which were considered fringe at the time. Numerous studies reported on lower therapeutic efficacy than had been expected, and neurofeedback was also perceived by many to be dangerously close to mind control. However, the 1990s and early 2000s brought a renewed interest in the method as computerized EEG became more easily accessible, and research in brain science was revitalized by numerous breakthroughs and the "Decade of the Brain" (Evans and Abarbanel 1999).

Neurofeedback for ADHD Today

Today neurofeedback is growing rapidly as a form of alternative treatment, marketed as a highly effective intervention for both therapy and personal growth (Demos 2005). There are two primary forms of receiving neurofeedback: either with a trained professional or by using commercial devices at home. Professional neurofeedback therapists usually perform an extensive quantitative EEG (qEEG) measurement at the first session, and the client's qEEG data is compared to a normative database in order to determine the specific training paradigm and electrode placement that will be used. Normative qEEG databases, such as the Neurometric Analysis System, have received FDA clearance (John et al. 1983), but they can only serve as aids to diagnosis, treatment planning, and follow-up. Recent reviews argue for a more prominent clinical role of qEEG in child and adolescent psychiatry (Chabot et al. 2005; Hirshberg et al. 2005). Neurofeedback therapists also produce a colorful "brain map" to visualize individual EEG characteristics, and ethnographic evidence shows that clients often find this visualization as well as the brain-based explanation of their symptoms highly convincing and compelling (Brenninkmeijer 2010).

ADHD in particular is understood to be related to under-arousal in frontal areas and cortical slowing, which means that children show an excessive amount of slow waves and a reduction in faster waves, which are associated with alertness and concentration (Monastra et al. 1999). Therefore the most common neurofeedback training method is to suppress slow, theta activity while increasing faster waves in the beta range. Various protocols have been developed that draw on this principle

(Monastra 2005), but recently researchers have used slow cortical potential (SCP) training paradigms as well (e.g., Heinrich et al. 2004). SCPs are event-related changes in cortical polarization that play a role in the preparatory distribution of attentional resources (Birbaumer 1999; Strehl et al. 2006). Other than theta/beta training, which aims at changing abnormalities in resting EEG and influencing the ratio of slow waves to faster waves in certain areas, SCP training aims at increasing cortical negativity and thereby improving cognitive control (Heinrich et al. 2004).

Considerable differences exist between neurofeedback systems in terms of the feedback they give. The simplest type provides a visual representation of the subject's EEG activity and sounds a tone when the desired patterns are produced. Others can be linked to a video or DVD player where the image size and resolution increase or decrease based on EEG activity. Go/No-Go systems employ simple video games, such as Pac-Man, where the player's character moves if appropriate waves are produced but freezes when the subject is not in the desired state. Still other systems can be connected to commercially available video games using Sony PlayStation or Nintendo X-Box consoles where the player's video game controller loses sensitivity or otherwise impedes gameplay if the subject is not in the expected brain state (http://www.smartbraintech.com). Most recently, researchers have begun to combine neurofeedback technology with immersive virtual reality environments (http://openvibe.inria.fr/a-bci-based-virtual-reality-solution-for-adhd-treatment-prototype/).

The FDA's 2013 decision to permit marketing of the first ever EEG diagnostic test for ADHD has received mixed reactions from experts. The system in question measures theta-beta ratio and produces a report to aid clinicians' evaluations but it is not intended to be a stand-alone method in diagnosis (http://www.fda.gov/newsevents/newsroom/pressannouncements/ucm360811.htm).

BCI games have also entered the commercial market (Cole 2007), and some of these games are advertised as effective tools for improving the symptoms of ADHD (e.g., FocusPocus, SmartBrain). Although neurofeedback professionals warn against unsupervised and one-size-fits-all use of the method (Hammond 2011), the practice of home neurofeedback is likely to grow, given that the method combines gaming with an ostensible therapeutic function. This may encourage both parents and children hoping for an effective alternative to drug treatment for ADHD (Fuchs et al. 2003).

Key Elements of an Ethical Framework: BCIS for ADHD

The following sections will discuss two foundational ethical issues – safety and efficacy of BCI technologies – and analyze four practical implications of these concerns: regulation and commercialization, responsible communication, identity considerations, and the enhancement use of BCIs. This is not, of course, an exhaustive presentation of ethical concerns that arise from BCI technologies. The focus on safety and efficacy is meant to provide the conceptual foundations for an ethical framework for the use of BCIs for ADHD in children. Considering that BCI

technologies for ADHD are still at an early stage of development, and are not widely used, it is unwise to indulge in a speculative ethics and to develop an account, which has little basis in evidence or in reality.

How Effective Is Neurofeedback?

Research on neurofeedback has been growing quickly since the mid-1990s, although the precise function of brain rhythms is still poorly understood (Frank 2009). Different sources offer differing accounts of the level of scientific support in favor of neurofeedback in the treatment of ADHD. While there is a considerable body of case studies that demonstrates equal or superior effectiveness compared to stimulant drugs, there are very few controlled and methodologically rigorous studies with large sample sizes. Furthermore, there is an ongoing debate in the literature about how the available scientific data should be evaluated and interpreted. In particular, reviewers disagree on the methodological robustness of available findings, and some critics question whether the observed positive effects of neurofeedback are really caused by EEG training and not other factors. In the past decade, the efficacy of neurofeedback for the treatment of ADHD has been reviewed on numerous occasions, with the various studies arriving at very different conclusions. The reviews and analyses most commonly refer to standardized systems of evaluation, such as the five-point scale of the American Psychological Association, used for the categorization of scientific evidence in support of different treatments, which ranges from “Not Empirically Supported” (Level 1) to “Efficacious and Specific” (Level 5).

Monastra and colleagues conducted the first review of case studies and controlled-group studies of neurofeedback in the treatment of ADHD. Although both case studies and controlled studies demonstrated beneficial effects of neurofeedback on the core symptoms of ADHD, the authors pointed out that studies had not been adequately blinded and thus could not control for expectancy and other nonspecific treatment effects. Still, the paper concluded that neurofeedback could be considered a Level 3 “probably efficacious” intervention for ADHD (Monastra et al. 2005). The same year, Loo and Barkley published a more critical evaluation of the method, in which they stated that neurofeedback studies for ADHD were either methodologically weak or they could not demonstrate superior efficacy compared to placebo or no-treatment control (Loo and Barkley 2005). The National Resource Center on AD/HD also published a non peer-reviewed online paper discussing eight major controlled studies that had been conducted through 2005 and concluded that neurofeedback for ADHD was a Level 2 “possibly efficacious” method (WWK 2008). The report also stressed the lack of proper randomization and inadequate blinding as the most important limitations of available studies while pointing out that some evidence suggests the use of neurofeedback for ADHD in schools could be associated with greater class inclusion and financial savings.

Hodgson and colleagues conducted a meta-analytic review of nonpharmacological treatments for ADHD, which included behavior modification, neurofeedback therapy, multimodal psychosocial treatment, school-based programs,

working memory training, parent training, and self-monitoring. Neurofeedback produced the largest average weighted effect size on outcome measures, and the authors concluded that it was the most efficacious evidence-based nonpharmacological intervention for reducing ADHD symptoms (Hodgson et al. 2012). However, this paper received criticism for neglecting recent research findings and for the small number of studies it included (Rothenberger and Rothenberger 2012).

In 2009, Arns and colleagues conducted a thorough meta-analysis, which included 15 studies and thus drew on a larger pool of findings than the earlier reviews. The authors came to the conclusion that neurofeedback for ADHD warranted the highest possible, Level 5 classification. Of the core symptoms of ADHD, Arns et al. reported high effect sizes of neurofeedback for inattention and impulsivity and medium effect size for hyperactivity (Arns et al. 2009). The meta-analysis looked at prospective controlled studies, prospective pre-/post-design studies and retrospective pre-/post-design studies, although they considered randomized and nonrandomized investigations together, which makes it difficult to draw solid conclusions. Although the authors acknowledged some methodological limitations that had been pointed out by earlier reviews, they still considered the available evidence strong enough to support neurofeedback as an “efficacious and specific” intervention. Understandably, neurofeedback service providers predominantly refer to this most favorable evaluation of the method.

An extensive review of studies through September 2010 by Lofthouse and colleagues articulated firm disagreement with the Arns et al. paper and claimed that neurofeedback for pediatric ADHD could only be considered “probably efficacious” and that a large, multisite, double-blind randomized control trial was necessary to settle the question concerning efficacy (Lofthouse et al. 2012a). The authors’ central criticism was that on the basis of current evidence it is not possible to establish whether the observed benefits are due to specific effects of neurofeedback or other nonspecific ones, such as “selection effects, participant history, regression to the mean, placebo response, maturation, practice with assessment measures, and/or participant–rater–experimenter expectancies” (Lofthouse et al. 2012a, p. 15). They also pointed out that studies did not sufficiently monitor the use of concomitant treatments that might have influenced outcomes and there was no reliable follow-up data available. Researchers also failed to report on any observed adverse effects, and there was considerable variability in the administration of neurofeedback both in terms of the specific systems and software used and in terms of treatment length and frequency (Lofthouse et al. 2012a).

In a subsequent review of studies since 2010 Lofthouse et al. acknowledged positive persistent benefits associated with neurofeedback and medium-to-large improvement. However, methodological concerns prompted the authors to maintain the position that available evidence did not support the time and money parents would have to invest into a course of neurofeedback treatment (Lofthouse et al. 2012b).

The possibility of proper blinding and sham control is of particular importance, and there has been disagreement in the literature about whether it is possible and/or ethical at all (Lofthouse et al. 2012a; Leins et al. 2007; La Vaque and Rossiter 2001), given that wait-list and placebo condition studies lasting several tens of

session are in conflict with the Declaration of Helsinki (World Medical Association 2000). An NIMH-funded feasibility study with 39 participants conducted by Arnold and colleagues found that proper blinding was indeed possible, that a sham-condition did not lead to high drop-out rates and that the optimal treatment frequency was 3×/week (Arnold et al. 2013). But the question concerning the feasibility of sham control is still unresolved. A true sham control should be inert, and in the case of neurofeedback, researchers have provided subjects with random feedback instead of feedback contingent on their EEG activity. However, the system does reinforce some activity it can still occur that it reinforces the desired EEG activity. Furthermore, the regular participation in a treatment setting as well as the repeated effort to pay attention during session might also produce some effects. A further complication is that all studies to date that used sham feedback found that both the active and control groups improved in primary ADHD symptoms with no significant differences between the two conditions, suggesting that the method is not better than placebo or that the main treatment effects are nonspecific. For such reasons, Loo and Makeig do not recommend the most commonly used theta/beta neurofeedback neither as a first-line nor as an adjunct treatment until there is convincing evidence that the method is superior to placebo or equally effective as established treatments. However, the authors note that SCP neurofeedback may prove effective as an adjunct therapy in a significant subset of children, but more research is needed to identify which methods are effective in which ADHD patient populations (Loo and Makeig 2012).

A further, complicating issue concerns the reliability of neurofeedback technology itself. Some studies suggest that EEG-based BCI technologies are limited by the spatial resolution at which brain signals are measured and they are also vulnerable to interference from facial muscles or blinking, movements that are all the more difficult to control by children (Zander and Kothe 2011).

In summary, there is a wide range of opinions about neurofeedback and different appraisals of the available studies. However, at this time, a majority of reviews are cautious about recommending neurofeedback for treatment of ADHD. A group of researchers comprising both neurofeedback experts and ADHD treatment outcome investigators is preparing a multisite double-blind sham-controlled study with follow-up assessments that might settle the question of efficacy (Lofthouse et al. 2012b).

Adverse Effects

While neurofeedback research can look back at a history of several decades, there is very little research about the long-term effects of the method and especially on its impact on developing brains. Although there are no reports of adverse side effects in the literature, and neurofeedback practitioners stress the methods' safety, there is no systematic evaluation of this issue (Rutger et al. 2012). There are several points in relation to possible adverse effects with respect to neurofeedback training for ADHD in particular.

First, more research is needed on what we might call the “ecology of brain waves”. For example, some research suggests that theta waves, which neurofeedback training often tries to decrease, play an important role in musical performance (Egner and Gruzelier 2003). Thus, while increasing or decreasing the rate of certain frequencies or changing their ratios, such as in the case of theta/beta, might prove beneficial from one perspective, it is not clear how that change could influence other capacities and activities (Baum 2011).

Second, many EEG biofeedback-based toys available on the commercial market today reinforce the generation of theta waves in order to win (such as Mindflex and Mindball). As already mentioned, children with ADHD already show elevated levels of theta, which may suggest that certain BCI games could actually exacerbate their symptoms.

Moreover, neurofeedback systems, which are attached to computer or video games (e.g., SmartBrain, Focus Pocus) raise an interesting question about the relationship between screen time and ADHD. Some research suggests that there may be an adverse connection between internet- and video-game use, and ADHD, such that the risk of addictive gaming behavior may be elevated and ADHD symptoms worsened (Weiss et al. 2011). The connection between gaming and ADHD needs more rigorous scientific evaluation to better assess the relative risks and benefits of this particular mode of intervention.

The repetitive use of certain brain pathways through EEG-type devices has unknown consequences for brain structure and function. The brain has been shown to be malleable through indirect influences such as learning; therefore, it is likely that the brain’s plasticity will be impacted by high use of interventions such as neurofeedback. Further research is necessary to better understand the impact of noninvasive BCI interventions over time and how these interact with the processes of brain development and maturation in children (Hildt 2010).

Finally, the Nuffield Council on Bioethics (NCOB 2013) notes that one of the most insidious risks of BCI technologies such as neurofeedback may be the psychosocial effects of disappointing results following high expectations. This concern is compounded by the relatively unregulated space that noninvasive BCIs inhabit. As the following section outlines, the lack of regulation has implications for both the marketing and the delivery of neurofeedback systems for ADHD, as well as, of course, consumer safety and autonomy.

Implications of Safety and Efficacy Considerations

Regulation and Commercialization

Commercialization of BCI devices for ADHD as well as for nonmental health conditions is currently running ahead of regulation strategies to manage the uncertainty surrounding these devices. In the case of neurofeedback, practitioners stress that the method needs to be administered by a trained professional and that it is definitely not a “kid’s toy” (Thatcher 1999). However, neurofeedback

is becoming exactly that as more and more companies are bringing neurofeedback systems for home use to the commercial market with almost no regulatory oversight.

In the United States, neurofeedback devices are considered Class II medical devices by the Food and Drug Administration (FDA). This is the middle category on the FDA's three level system of classification, which is based on potential risks and harms. The FDA has cleared the use of neurofeedback devices in 1976 for relaxation and muscle reeducation only. A specific type of device, namely, a "prescription battery powered device that is indicated for relaxation training and muscle reeducation" (http://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfcfr/cfrsearch.cfm?fr=882.5050) was granted 510 k exempt status, which means that manufacturers of such devices do not have to file a (510 k) Premarket Notification to the FDA before bringing their product to the market. Manufacturers are still required to register with the FDA, and any device that is different from the above still has to obtain FDA clearance. The FDA has accepted Premarket Notification for a number of EEG biofeedback devices, which have been deemed "substantially equivalent" to those marketed in 1976 or before. This means that neurofeedback cannot be promoted as a treatment for conditions like ADHD, but professionals can use the devices as part of their practice for numerous off-label purposes. However, if any new device received FDA clearance with an indication for ADHD, then all other devices deemed substantially equivalent would receive the same clearance as well, although considerable differences exist between the various systems in terms of their technical features, software, and training paradigms.

The European Union has three Directives that regulate medical devices, of which one is relevant to noninvasive BCI technologies. The underlying objectives of these Directives are to ensure safety and efficacy of the devices, as well as to remove barriers to trade within the EU. Companies must demonstrate that a device meets the requirements of a given Directive to receive the CE-mark, which is widely held to be a guarantee of quality, although it is not.

In the USA and the EU, medical devices can only be sold to licensed health care practitioners, and their sale must be reported to relevant national "competent authorities" such as the FDA and, in the UK, the Medicines and Healthcare Products Regulatory Authority (MHRA). However, an increasing number of noninvasive BCI technologies are delivered via a nonmedical route. Neurofeedback BCI devices are available to private individuals, numerous toys and video games that draw on similar technology are being brought to market, and many more can be expected in the near future (Nijboer et al. 2011). Because these are commercial products not marketed for medical purposes, they are not regulated by the FDA or the EU Directives. Direct-to-consumer (DTC) advertising is not covered by any of the EU Directives, nor does the FDA regulation on DTC advertising cover nonmedical devices.

It is unclear which range of private individuals and professionals will choose to use noninvasive BCI technologies. It is also unclear who the consumers of such technologies will be. Yet "brain training" aimed particularly at individuals with memory and attention difficulties is offered to children and families via private

clinics and on the Internet. The educational sphere may also be impacted: on the Internet, toys are sometimes marketed as tools that schools can use to improve the performance of easily distracted children (see http://www.vivifeye.com/) without firm scientific support for such claims (Foks 2005; Plischke et al. 2011).

Without adequate oversight and evidence the use of BCI technologies for ADHD might carry certain risks, especially if administration is undertaken in the absence of trained professional supervision. In the case of neurofeedback, there are no established criteria for what constitutes appropriate and inappropriate use and what kind of education and training is necessary to provide neurofeedback. At present, health care professionals can offer neurofeedback as part of their services without any special training. Although professional organizations like the Association for Applied Psychophysiology and Biofeedback (AAPB) offer certification, it is not required to practice. For this reason, some have argued that neurofeedback should ideally be limited to the clinical domain and practiced only by physicians and clinical psychologists (Giordano and DuRousseau 2011). Furthermore, neurofeedback professionals' guidelines firmly stress the importance of purchasing FDA-cleared equipment and using these within the scope of the individual's license; however, not all professionals abide by these rules (Striefel 2009).

A precautionary view considers the increasing commercialization of BCI technologies like neurofeedback to be problematic both from an ethical and a scientific perspective. There is limited understanding of the precise mechanisms through which different technologies exert effects, and effects on the developing brain are largely unknown. Given that considerable differences exist between various neurofeedback systems, mechanisms, and effects, these have to be defined more clearly in order to achieve differential regulation. This position urges a precautionary approach as well as stronger governmental oversight and mechanism to evaluate claims about safety and efficacy (Tamburrini 2009; Plischke et al. 2011).

The UK Nuffield Council on Bioethics' Report on Novel Neurotechnologies is the first to outline a substantive approach to the regulation of noninvasive BCIs and other novel neurotechnologies (forthcoming). The approach draws on an ethical framework that incorporates the precautionary principle but also recognizes the need for innovation in the area of novel neurotechnologies. The Nuffield framework seeks to balance the uncertainty surrounding current BCI technologies and the real need of patients suffering from complex, chronic brain diseases that cause significant mental, physical, and emotional suffering to individuals and their families. Many of the recommendations in the report involve soft regulation, in an effort to encourage both caution and innovation in the development and application of BCI technologies. Further discussion and debate are now necessary to achieve a sound policy approach to the regulation of BCI technologies; eventually more oversight and evaluation are certainly necessary (van Est et al. 2010). Strict guidelines, policies, and laws that are informed by neuroethical analyses and based upon neuroscientific information are required to guide the dissemination of neurofeedback-based devices in the public sphere (Giordano and Olds 2010). However, in the case of neurofeedback, this neuroscientifically informed

neuroethical analysis is complicated by the fact that currently no scientific consensus exists about the benefits of neurofeedback training. This lack of consensus is all the more pressing because consumers are already exposed to various, sometimes contradictory and often exaggerated claims about the method, which highlights the importance of responsible communication.

Responsible Communication and Neuroliteracy

Unlike psychostimulant drug therapy for ADHD, which can only be prescribed by medical doctors, private practitioners offer neurofeedback services, and BCI devices are already available commercially. Consumers of both professional neurofeedback training and commercial EEG-based products are therefore exposed to various claims about the method's efficacy and safety. A course of neurofeedback training can be a significant financial commitment over a lengthy period of time that despite hope-inspiring claims may not produce the desired outcomes (Lofthouse et al. 2012a). These factors foreground the relevance of responsible communication about and strict evaluation of novel neurotechnologies. Some argue that it may be ethically unsound to "market brainwave interface products as toys, games, and educational aides, without consideration of the possible, if not likely, consequences of putting BMNs [brain machine neurotechnologies] into the hands of consumers who do not realize the actual capabilities, as well as risks and harms, of these products" (Plischke et al. 2011, p. 224). BCI researchers have also argued that ethically sound, responsible communication and appropriately balanced media reporting are crucial (Nijboer et al. 2011).

Furthermore, although neurofeedback practitioners are expected to provide accurate and credible information about the method to their clients, and to continuously educate themselves about scientific developments (Striefel 2009), heated disputes surrounding the method make it rather difficult to achieve this clarity. In fact, service providers often cite only the most favorable reviews about the method. For example, the Association for Applied Psychophysiology and Biofeedback (AAPB), the first professional organization dedicated to biofeedback, does not list any research articles dated 2009 or later on its publicly available website, although several studies and reviews have been published since then. Furthermore an AAPB report from 2004 includes a long list of conditions alongside the level of biofeedback's clinical efficacy for that condition. This list includes ADHD and claims that EEG biofeedback is a Level 4, "efficacious intervention" (Yucha and Gilbert 2004) despite intense debates about such claims.

While stricter guidelines for neurofeedback professionals and device manufacturers are certainly necessary, the wider public may also need to become more neuro-literate. It is becoming increasingly important to gain basic familiarity with neuroscience, because as parents, teachers, and professionals, individuals confront arguments clad in neuroscientific terms for and against various technologies, products, therapies, educational approaches, and a whole host of other things. As neuroscience gains an ever more prominent role in shaping our understanding of the most diverse aspects of the human condition, "neuroliteracy" on the part of the wider public would contribute greatly to making more informed choices and decisions in the vast sea of claims and promises (Farah 2011).

Identity and Brain Interventions

An important consideration that flows from the discussion of efficacy of BCI technology for ADHD is the potential implications for identity. The ethical discussion of identity, intervention, and ADHD has taken place largely in relation to stimulant drug treatments. Here, the developmental dimensions of BCI technologies become particularly acute, as there is a substantive difference in ethical concerns between children and young people on the one hand and adults on the other.

Treatment of ADHD with stimulant medications has given rise to a passionate debate about the effect of such drugs on children's developing sense of self and moral identity. Critics have argued that children are drugged into obedience and conformity, which thwarts their moral development. Yet, recent research both from the social and natural sciences says that at least some of these fears are unfounded (Singh 2013; Hyman 2013). In fact, many children feel empowered to behave as moral agents and to better meet the expectations of their social environments with medication. Of course, this does not mean that the practice of treating children with psychostimulants is entirely unproblematic (Caplan 2013).

Like psychostimulants, BCI technologies explicitly aim to affect neural mechanisms putatively correlated with the capacity for cognitive self-control. Although neurofeedback is often portrayed as a way of learning to take control over brain activity, it is not entirely clear how much conscious effort is needed on the part of the child who is undergoing neurofeedback training, which is based on the principles of operant conditioning. In fact, some ethnographic evidence suggests that subjects need to engage in minimal effort and should remain passive observers of the process of retraining their brains. The literature often reports of the transformative power of the method, as it restores selves thought lost to disease or transforms one's self as symptoms of disorders improve (Brenninkmeijer 2010).

While drug therapy has provoked intense discussions and polarized opinions, neurofeedback is sometimes discussed as "crackpot charlatanism" and sometimes as a panacea (Ellison 2010), but it has not been addressed as an intervention that would somehow interfere with moral capacity and self-governance. This is somewhat remarkable, considering the fact that both methods operate directly on the brain to bring about potentially transformative effects. Neurofeedback thus provides an interesting opportunity to study the factors that might give rise to moral concern about a particular intervention. Are drug-based interventions more prone to criticism and moral concern than novel neurotechnologies? If so, why? Such questions cannot be answered on the basis of conceptual analysis alone and are in need of empirical evidence.

Enhancement

As already argued, the lack of biomarkers for diagnosing ADHD blurs the boundary between the treatment of symptoms and the enhancement of cognitive capacities. Performance enhancement and peak performance training have been important applications of neurofeedback since the 1970s. According to some evidence, the method can be used to improve artistic, cognitive, and sports performance, although efficacy is still debated and needs more thorough investigation (Vernon 2005;

Gruzelier et al. 2006; Keizer et al. 2010). The increasing commercialization of the method (see http://www.emotiv.com) and online platforms, such as OpenEEG, (http://openeeg.sourceforge.net) further complicate the ethical evaluation of neurofeedback for performance enhancement. The method's broad availability and the likely demand for performance enhancement put an increased emphasis on the need for careful scientific evaluation of adverse and long-term effects and highlight the need for ongoing societal deliberation about maximizing the benefits and minimizing the risks of novel neurotechnologies.

Conclusion

Although neurofeedback has been around for many decades, it is currently undergoing an explosion in both popular and scientific interest. Several companies are racing to bring new BCI products to the market in sectors ranging from medical diagnostics and assistive solutions, through gaming and entertainment, to neuromarketing. This trend is very likely to continue into the future as the technology becomes cheaper, more sophisticated and readily available. Open-source hardware and software projects contribute a lot to making BCIs more widely accessible. However, the jury is still out on whether neurofeedback is an effective and specific method of improving performance in ADHD in particular. The scientific literature is inconclusive and there is little understanding of both the mechanisms of action and possible adverse effects. Contradictory evaluations of available findings make it difficult to arrive at any solid conclusions, which is especially problematic given the method's increasing commercial availability in the form of toys, games, and educational aids. These are often aimed specifically at children with ADHD. These uncertainties highlight the importance of further targeted research and responsible communication about the method. They also bring to the fore the growing need for the wider public to gain a basic understanding of neuroscience to make informed decisions about available interventions. Furthermore, some aspects of the current medical device regulatory framework and the lack of oversight over commercial products are problematic. As numerous authors have argued, straightforward policies, based on neuroethical analyses and informed by neuroscientific knowledge, are urgently needed. Neurofeedback's easy availability might make it less apparent that a wide range of questions and concerns surrounding the method are still unresolved, which underlines the importance of a broader engagement with the topic.

Real-Time Functional Magnetic Resonance Imaging–Brain-Computer Interfacing in the Assessment and Treatment of Psychopathy: Potential and Challenges

47

Fabrice Jotterand and James Giordano

Contents

Abstract

This chapter focuses on the engagement of real-time functional magnetic resonance imaging-brain-computer interfacing (rtfMRI-BCI) in the treatment of psychopathy and some of the more pertinent ethico-legal and social issues fostered by such use of this neurotechnological approach. To this end, we first provide an overview of the nature of psychopathy. Second, we pose the premise that given the paucity – if not frank absence – of effective psychopharmacological treatment(s) or rehabilitation strategies presently available for psychopathy, it becomes important to examine the present state of neurotechnologies that

might be used to effect potential benefit in the treatment of this disorder and focus this examination upon the possible utility of rtfMRI-brain-computer interface technology. Third, we present an overview of those tools that are currently used to determine and diagnose psychopathy and discuss their limitations. Finally, we address the major ethical questions and issues arising from the use of this technology to modify behavior in individuals with psychopathic traits.

Introduction

Advances in neuroscience and neurotechnology have increased the capability to assess and manipulate the brain. The use of neurotechnologies to depict, define, and evaluate neural systems' structure and function has expanded the fund of extant knowledge and, as noted by sociologist Bruno Latour (1987), in so doing has prompted additional and perhaps more incising questions about the nature of consciousness, emotions, free will, morality, and constructs of mind and self. Several neurotechnologies are currently employed in clinical, legal, and social contexts; at present, these include (1) neuroimaging, which is being increasingly employed – albeit with considerable criticism – in forensics (e.g., lie detection); (2) neurostimulation technologies, which have been engaged to provide non-pharmacological treatments for a variety of neuropsychiatric disorders (e.g., Parkinsonism, treatment-resistant depression, chronic pain); and (3) those neurotechnologies that are currently in use and being developed to increase cognitive performance (e.g., "cognitive tune-up" [Ong 2008]; "aug-cog" military applications [McBride and Schmorrow 2005; for extensive overview of the use of neurotechnology in military and national security and defense applications, see the thematic issue of *Synesis*: *A Journal of Science*, *Technology*, *Ethics and Policy*, 2010(2)]), to control motor activity, and/or modify behavior (i.e., treatment of psychopathy [Sitaram et al. 2007; Vaadia and Birbaumer 2009]). This chapter focuses on the engagement of real-time functional magnetic resonance imaging-brain-computer interfacing (rtfMRI-BCI) in the treatment of psychopathy and some of the more pertinent ethico-legal and social issues fostered by such use of this neurotechnological approach. To this end, we first provide an overview of the nature of psychopathy. Second, we pose the premise that given the paucity – if not frank absence – of effective psychopharmacological treatment(s) or rehabilitation strategies presently available for psychopathy (Ogloff and Wood 2010; Harris and Rice 2006), it becomes important to examine the present state of neurotechnologies that might be used to effect potential benefit in the treatment of this disorder and focus this examination upon the possible utility of rtfMRI-brain-computer interface technology. Third, we present an overview of those tools that are currently used to determine and diagnose psychopathy and discuss their limitations. Finally, in the spirit of Latour, we address the major ethical questions and issues arising from the use of this technology to modify behavior in individuals with psychopathic traits.

Psychopathy

Psychopathy[1] is a highly investigated personality disorder; yet, to date, an effective treatment for this condition, which is characterized by emotional dysfunction and antisocial behavior, remains lacking (Ogloff and Wood 2010; Harris and Rice 2006). While partially overlapping as a diagnostic construct with antisocial personality disorder (ASPD), the two conditions are, in fact, not identical because ASPD shares a number of comorbid characteristics with other disorders characterized in the *Diagnostic and Statistical Manual* (*DSM*) of the American Psychiatric Association (now in its fifth edition, the *DSM*-5; American Psychiatric Association, www.dsm5.org), and there is a general tendency for overuse of crime-related indicators in ASPD (Widiger 2006). However, while psychopathy is included in the *DSM-5* under the Antisocial/Psychopathic Personality Disorder Type, it is worth noting that individuals with psychopathic traits do not necessarily display criminality. To be sure, psychopaths can manifest antisocial behavior and, by definition, lack emotional response to negative stimuli, yet these traits can and often do occur without prompting criminal activities, as personified by Sam Vaknin in the documentary *I*, *Psychopath* (Lykken 2006; *I*, *Psychopath*, http://topdocumentaryfilms.com/i-psychopath/).

Based on the *Psychopathy Checklist*: *Screening Version PCL*, psychopathy affects approximately 1–2 % of the general population (Neumann and Hare 2008). Symptoms of psychopathy include emotional and interpersonal superficiality, egocentricity and grandiosity, lack of remorse or guilt, lack of empathy, deceitfulness and manipulation, and shallow emotions. The disorder also entails social deviance, manifested in impulsivity, poor behavior controls, need for excitement, lack of responsibility, early behavior problems, and adult antisocial behavior (Hare 1999). According to Kiehl (2006), psychopathy alters cognitive and affective functions in ways that evoke deficiencies in three primary domains: (1) language (i.e., abnormalities in processing abstract or emotional word stimuli), (2) attention and orienting processes (i.e., lack of fear conditioning and unresponsiveness to potential threat(s) of punishment), and (3) affect and emotion (i.e., lack of empathy, guilt or remorse, shallow affect, and irresponsibility and behavioral characteristics such as impulsivity, poor behavioral control, and promiscuity). While only between 15 % and 30 % of the male and female prison population are psychopaths, these individuals have been shown to commit 50 % more crime than non-psychopathic inmates (Sitaram et al. 2007). As well, psychopathy is considered to be a major predictive variable of criminal recidivism. It is estimated that psychopathic offenders are approximately four (4) times more likely to re-offend than non-psychopathic offenders (Hemphill et al. 1998; Fine and Kennett 2004).

Psychopathy is being viewed as paradigmatic pathology for which to use emerging neurotechnologies to define and predict neuropsychiatric disorders of cognition, emotion, and behavior. In this way, the utility and value of neurotechnologies may

[1]This section was adapted with permission from a book chapter: Jotterand et al. (2013)

be (1) in assessing potential predisposition(s) for antisocial and/or criminal acts and (2) used as part of an interventional protocol aimed at preventing such acts. Without doubt, some psychopaths are criminals who need psychiatric treatment. Other individuals have psychopathic traits but have not (as yet) committed criminal acts. Both types of individuals could be a potential threat to society: the former because of their criminality and disposition for recidivism and the latter because of the putative risk(s) fostered by their neuropsychiatric condition. In this light, neurotechnology (e.g., co-registered neuroimaging coupled to neurogenetics and phenotypic markers) could be used to reveal neurobiological traits that may be important to a multicomponential diagnostic protocol, which, if shown to be valid, effective, and reliable, might be ethically and legally justifiable to prompt apprehension and intervention of identified individuals prior to the commission of antisocial, violent acts (Blair 2007, 2008; Birbaumer et al. 2005; Dumit 2003; Deeley et al. 2006; Yang et al. 2009; Blonigen et al. 2003, 2005; Viding et al. 2005; Larsson et al. 2007; Kim-Cohen et al. 2006; Giordano 2011a, b).

As regards intervention, it is important to note that the lack of effective treatment and/or rehabilitative options for psychopathy constitutes a significant challenge for psychiatry, society, and, particularly, for prison administrations. Currently used psychopharmacological interventions are ineffective (Salekin 2002), and subjects who have undergone behavioral therapy fail to exhibit any substantive change in behavior or reduction(s) in recidivism (Abbott 2001; Harris and Rice 2006). Neurotechnologies such as real-time functional magnetic resonance imaging coupled to brain-computer interfaces (rtfMRI-BCI) could provide an alternative approach in the treatment of psychopathy (Sitaram et al. 2007; Vaadia and Birbaumer 2009), yet this is not without limitations, burdens, and potential risks, as we herein seek to illustrate. Although space constraints limit a definitive analysis of rtfMRI, any discussion of rtfMRI-BCI technology, both in general and more specifically for the treatment of psychopathy, must recognize that this approach is in early phases of development and testing, and therefore, further data are required before any conclusive assessment of its viability and ultimate value can be definitively provided. Consequently, this chapter is limited to an overview analysis of the ethical issues arising from the use of rtfMRI-BCI in the determination and diagnosis of psychopathy (and the implications and utility of this neurotechnology in defining subsequent trajectories of intervention), as based on the current information available about both the condition of psychopathy and the state of development and utility of the neurotechnology.

The Possible Utility of Present and Future Neurotechnologies

Functional MRI-BCI constitutes a system that conjoins four major components: the participant, the signal acquisition, the signal analysis, and the signal feedback. Individuals undergoing fMRI-BCI procedures are trained to regulate brain activity by combining "contingent feedback and mental strategies" (Sitaram et al. 2009). This technology-based approach is being developed for the treatment of

psychopathy and other disorders of cognition, emotions, and behavior (e.g., modification of deviant sexual interests in pedophilia [Renaud et al. 2011]). The proposed basis of therapeutic effect(s) is the capacity for individuals to activate and reinforce particular patterns of neural network activity in those brain areas putatively associated with specific types of (favorable or rectified) behaviors (Sitaram et al. 2007; Vaadia and Birbaumer 2009). Various studies using fMRI-BCI technology have provided evidence of behavioral changes in neural network activity in brain areas associated with the perception of pain (e.g., the rostral anterior cingulate cortex [deCharms et al. 2005]), language processing (e.g., the right inferior frontal gyrus [Rota et al. 2008]), and response to certain emotional stimuli (e.g., the anterior insula [Caria et al. 2006, 2007; Sitaram et al. 2009]). A 2005 study by Birbaumer et al. revealed that criminal psychopaths showed a lack of metabolic activity in brain areas associated with mediating fear that are usually activated during aversive classical conditioning (i.e., fear of punishment in which fear conditioning is essential for behavioral development; Birbaumer et al. 2005). It has been hypothesized that fMRI-BCI technology could be utilized to condition psychopaths to activate brain regions involved in fear-evoking situations and, in this way, engage a form of neurofeedback that may be effective in reducing psychopathic traits (Birbaumer and Cohen 2007; Sitaram et al. 2007). This hypothesis is fortified by a 2007 study demonstrating that criminal psychopaths can be conditioned to self-regulate emotions through feedback-induced alteration of the blood oxygen level (BOLD) signal (and by implication, neural network activity) in the anterior insular cortex (Sitaram et al. 2007, 2009).

These findings – while limited and nascent – are suggestive, if not promising, and current interest in this area mandates further analysis of the potential use of rtfMRI-BCI, and other neurotechnologies, to alter the human predicament (of disease, illness, suffering, and sadness), the human condition, and perhaps human beings as well (Jotterand 2008a, b, 2010; Giordano 2010, 2012a, b, d). The use of rtfMRI-BCI for regulating "moral emotions" (Charland 2009) suggests the possibility of employing neurotechnologies to modify human thought and action. Studies have shown that human emotions and behavior may, in fact, be manipulated through a variety of neuroscientific approaches, including systemic and intraneural administration of a range of drugs and neuromodulatory agents (see Harmer et al. 2003; Kosfeld et al. 2005 for specific studies) and the use of neurotechnological devices (such as transcranial magnetic stimulation (TMS) deep brain stimulation (DBS) and vagal nerve stimulation; Horstman 2010; Ong 2008; Higgins and George 2009). Given these findings, it has been suggested that similar approaches could potentially be used to influence moral behavior (Blair 2007). Thus, we could envision trajectories toward neuro-engineering "morally better people" and/or reforming "morally deficient people" (e.g., psychopaths or incarcerated criminals; see Sitaram et al. 2007). Obviously, important steps toward the development and use of any such approaches would entail (1) reliable assessment, diagnosis, and/or prediction of aberrant cognition, emotions, and behaviors and (2) the use of neurotechnology to accurately depict the neural substrates and mechanisms subserving these cognitions and behaviors.

Tools for Diagnosing Psychopathy and Their Limitations

At present, three diagnostic tools are available for the determination of psychopathic traits or clinical psychopathy: (1) the Psychopathy Checklist–Revised (PCL-R), (2) neuroimaging techniques, and (3) neurogenetics. Robert Hare developed the Psychopathy Checklist – Revised (PCL-R) (Hare 1991) that empirically established the validity of a rating scale for psychopathy. Hare's empirical studies segregate four symptom clusters representative of psychopathy: *Interpersonal*: manifested by presentation of glibness/superficial charm, grandiose sense of self-worth, pathological lying, and cunning/manipulative traits; *Affective*: evidenced in lack of remorse or guilt, shallow affect, callousness, lack of empathy, and failure to accept responsibility; *Lifestyle*: a need for stimulation, proneness to boredom, parasitic lifestyle, lack of realistic long-term goals, impulsivity, and general irresponsibility; and *Antisocial*: effected by poor behavioral controls, early behavioral problems, juvenile delinquency, revocation of conditional release, and criminal versatility.

Neuroimaging technologies may provide additional means to determine neuroanatomical variations in brain structure and function that may be reflective – or predictive – of psychopathy (Harenski et al. 2010). Structural magnetic resonance imaging (sMRI) measures brain volume as based upon the paramagnetic signal expressed by relative densities of gray and white matter and provides fine spatial resolution and replicable data sets. However, a limitation of sMRI is that the image is static, which, while (rather precisely) depicting brain structure, does not illustrate any functional parameters. Functional magnetic resonance imaging (fMRI) measures blood flow in specific brain regions through depiction (and statistical parametric measurement, conversion, and analysis) of the differential paramagnetic signal produced by oxygenated and non-oxygenated hemoglobin (i.e., blood-oxygen level-dependent response, BOLD) as a function of variations in regional cerebral oxygen demand evoked by activity within particular neural networks in various brain regions. While this approach offers excellent spatial resolution, it affords only moderate (if not poor) temporal resolution in light of the time frame of neural vs. cerebrovascular events and consequences (NB: this is reflected in the caveat regarding fMRI-based assessment that is colloquially expressed as "fMRI measures *vein* activity, rather than *brain* activity"). In contrast, electroencephalographic recording/event-related potentials (EEG/ERP) assess the electrical activity of the brain through extracranial electrodes and provide superior temporal resolution, albeit with poor spatial resolution (a detailed examination of EEG-based techniques is beyond the scope of this chapter; for overview, see Niedermeyer and da Silva 2004; Huizenga et al. 2001; Hämäläinen et al. 1993; and for discussion of use and utility in forensic psychiatry, see Puranik et al. 2009).

Despite relative constraints and limitations, these techniques have proven useful in showing aberrant patterns of activity in neural networks, in particular brain regions of individuals with psychopathic tendencies (Blair 2008). Recent neuroimaging studies support that the abnormal psychophysiological and cognitive characteristics of psychopathy have definable neurobiological correlates (Pridmore et al. 2005; Raine and Yang 2006). Such investigations suggest that damage to the orbitofrontal

cortex may be associated with cognitive impairments (Kiehl 2006) and insult to the anterior cingulate can lead to emotional blunting, hostility, irresponsibility, and disagreeableness. Furthermore, abnormalities in the structure and/or function of specific regions of the amygdala, and afferent and efferent networks involving the amygdala, may subserve inappropriate responses to affective stimuli such as anger and/or fear expressed by others, which is often a cardinal trait of psychopathic individuals (Mesulam 2000; Aggleton 1992; Anderson et al. 2000; cited in Kiehl 2006). Taken together, results such as these support that neuroimaging may be of value in assessing and detecting neuroanatomic and neurophysiological variables that are diagnostic and perhaps predictive of aberrant cognitions, emotions, and behaviors that are representative of psychopathy.

Studies have also suggested a possible genetic contribution to psychopathy (Harenski et al. 2010), although the nature of genetic-environmental interactions and effects are not well defined (see, e.g., Ridley 2003, for review). Twin studies using the Psychopathic Personality Inventory revealed moderate-to-high heritability of psychopathic traits (Blonigen et al. 2003; see also Blonigen et al. 2005). A twin study by Viding and colleagues (2005) investigating the heritability of callous-unemotional traits and antisocial behavior suggested an influence of genetic factors in behavioral characteristics, and genetic studies found association between functional polymorphisms in the monoamine oxidase A (MAO-A) gene and conduct disorder (Harenski et al. 2010; see also analysis by Kim-Cohen et al. 2006). Other studies have examined correlation of MAO-A levels and traits that are representative of and/or prevalent in psychopathy (such as aggression and impulsivity; Buckholtz and Meyer-Lindenberg 2008), and a neuroimaging-genetic study found that males with low levels of MAO-A gene and enzyme had lower amygdalar volume and increased ventromedial prefrontal volume as compared to males with higher levels of MAO-A gene and enzyme (Meyer-Lindenberg et al. 2006). These studies infer that particular genetic variations may be involved in, and contributory to anatomical features that are observed in psychopathy and that these genetic and anatomical features may be validly and reliably assessable using current (and planned) neuroscientific and neurotechnological means. However, caution is warranted when proposing any form of definitive genetic and anatomic reductionism, i.e., establishing a wrong correlation between genes and behavior. Given the polymorphic and/or pleiotropic (multiple phenotypic) nature of neuropsychiatric disorders, the presence of specific genes is not sufficient to establish the primary cause of behavioral and/or psychological traits, as multiple genetic, anatomical, and environmental factors and interactions are critical (both at key developmental periods and to varying extent throughout the life span) to the spectral expression of a condition or disorder, inclusive of psychopathy (Giordano and Wurzman 2008; FitzGerald and Wurzman 2010; Wurzman and Giordano 2012).

These caveats are important in light of (1) an increasing trend toward employing neuroscientific and neurotechnological approaches such as neuroimaging and neurogenetics to define, assess, and determine a variety of cognitive, emotional, and behavioral characteristics; (2) existing strengths and limitations of these approaches; and (3) a call to use such approaches in ways that can prevent potentially

violent manifestations of particular psychiatric disorders, such as psychopathy. Thus, we urge the need to realistically and clearly elucidate (1) if and how such approaches might be used to validly and reliably detect and perhaps predict psychopathic traits and (2) what criteria must be developed, addressed, and satisfied in order to ethically and legally substantiate using neurotechnologies in these ways. These requirements compel the type of broad analysis of the neuroscience of psychopathy and the neuroscientific and neurotechnological approaches that could be employed to assess and intervene against the socially destructive traits of this disorder that we cannot provide given the space allocated. To wit, in what follows, we will focus our examination upon the ethical challenges arising from the proposed use of rtfMRI-BCI to assess – and shape intervention against – psychopathy.

Potential Ethical Concerns

The ability to assess, access, and manipulate behavior through rtfMRI-BCI has been advanced by a limited number of studies that have demonstrated positive behavioral changes (Caria et al. 2012). Thus, while these studies are restricted in scope, the implications drawn from their results are that this neurotechnology represents a promising, complementary, and perhaps even alternative approach to the use of existing, rather ineffective, interventions. Beyond these positive developments, further, more detailed and longitudinal studies are required to ascertain both the effectiveness and viability of this neurotechnological approach and to consider important issues that are related to current neuroscientific research on psychopathy, the technical and methodological challenges posed when attempting to utilize neuroscientific techniques and tools in assessing and treating this disorder, and the ethico-legal and social implications generated by these approaches. As with other new and cutting-edge technologies, there is considerable risk of overstating the potential applications and effectiveness of rtfMRI-BCI, and this incurs a number of ethical issues and problems. Questions such as honesty and veracity about the actual capabilities (and limitations), and the intended goals of employing rtfMRI-BCI, require careful analysis and articulation, so as to avoid misrepresenting what the technology can truly achieve and what various user groups (e.g., within medical institutions, prisons etc.) can offer to those treated and to society at large. For example, particular methodological issues related to the assessment of behavioral effects while using rtfMRI-BCI technology pose a twofold challenge, namely, (1) what methods can and should be used to validly correlate the activity and regulation of neural networks to specific cognitive, emotional, and motor effects and (2) can – and/or how can – subjects be conditioned to regulate BOLD responses to affect patterns of neural network activity and particular cognitions, emotions, and behaviors (Sitaram et al. 2009)? These questions, while fundamental to the value of rtfMRI-BCI-based approaches in assessing and treating psychopathy, are not insurmountable. Instead, we posit that issues such as these provide sentinel direction(s) for continuing research toward more finely grained elucidation of the substrates and

mechanisms of psychopathy and how this technology – and others – might be (best) used for neural network activation and behavioral control.

Still, there are additional challenges that raise ethical and social questions about such use of rtfMRI-BCI: Neuroimaging studies have been performed on relatively few psychopaths because of the difficulty in recruiting individuals that "truly" present with this disorder (i.e., exceed a threshold of 30 or higher on the PCL-R) (Harenski et al. 2010). As well, psychopaths often manifest comorbidities such as substance abuse and dependence, which can alter function of certain brain regions (e.g., the orbitofrontal cortex) that have been implicated in neuroanatomically based diagnoses of psychopathy (Harenski et al. 2010). Furthermore, developmental and longitudinal neuroimaging studies that would be important, if not necessary, to determine possible neural variation(s) and abnormalities in psychopathy are lacking (Harenski et al. 2010). To this point, it remains unclear whether neurobiological variations are the *cause* of psychopathy, whether they are an *effect*, or whether they are simply epiphenomenal. Central to this issue is the question of whether and to what extent genetic influence and/or the development of – or insult to – neuroanatomical structures and functions contribute to, and can be assessed as definitive and predictive of, psychopathy. Blair has asserted that there is always risk that "...a brain scan diagnosis of psychopathy legitimizes the preventive incarceration of a 'high-risk' individual, and in which a static neuro-structural deficit may lead to a therapeutically nihilistic approach to such an individual on the grounds that he is beyond rehabilitation" (Blair 2003, p. 564). Considering the lack of effective treatment for psychopathy, and current limitations of neurogenetics and neuroimaging, Blair's statement well-defines potential pitfalls of employing currently available neurogenetic and neuroanatomical methods – either alone or in tandem. Yet, recent events (e.g., Columbine, Phoenix, and Connecticut shootings) have prompted renewed public interest in – and calls for – the use of neuroscientific, neurotechnological, and psychiatric measures to better define, if not predict and prevent, violent psychopathic behaviors. The key questions then are whether and how neurotechnologies such as rtfMRI-BCI can – and should – be used for social control and to protect the public and what measures of analysis and scrutiny are necessary and sufficient to enable (technical and ethico-legally) prudent interventions. In other words, as neurotechnologies are developed and advanced, and the scope of their application increases, various stakeholders will need to determine (1) whether society has a moral obligation and legal duty to protect its citizenry through the development and use of neurotechnologies to "fix the defective brain" of psychopaths and (2) the source and validity of metrics that undergird and uphold social justification for (a) the use of predictive neurotechnologies, (b) the use of preventive measures prior to the commission of frank social violence, and (c) the enforced treatment of criminal psychopaths and/or enforced diagnosis (and uses of preventive interventions) in noncriminal psychopaths. The absence of effective psychopharmacological treatment and/or rehabilitation strategies also raises issues of how to determine and establish the ethical parameters (and boundaries) needed to (1) enforce therapy as condition for parole and decreased sentencing (of criminal psychopaths), (2) engage a sanctioned program of neuroenhancement (i.e., to

"neuro-engineer" the abolishment of psychopathic traits in those who could pose a threat to society), or (3) institute preventive measures so as to detect and avert socially aggressive and violent behavior in previously undiagnosed psychopaths. This in turn will require an assessment of current governmental regulations and the norms and values required (and used) to secure the safe utilization of neuroscientific and neurotechnologically based sociomedical interventions.

Personal Identity

The technical, methodological, and social questions and ethical implications raised in the previous section demand comprehensive investigation so as to avoid the misuse or abuse of neurotechnology. The focus on psychopathy increases the level of complexity because of the ongoing debate about the nature of the condition, i.e., how and to what degree it affects individuals who may or may not engage in criminal acts, and the moral and legal status of criminal psychopaths. This latter point necessitates questioning whether criminal psychopaths are responsible individuals, albeit diminished in their moral sensitivity due to neuroanatomical abnormalities and genetic determinants, thereby deserving criminal sentencing, or whether they are what Fine and Kennett refer to as "blameless offenders" (Fine and Kennett 2004) who instead should be required to undergo treatment in light of the "disease" or "disorder" of abnormal brain structure and/or function (see Jotterand et al. 2013, in press) for further analysis of this point).

The formulation of meaningful answers to these questions is dependent to a large part upon continuing neuroscientific research that is dedicated to further an understanding of psychopathy. An unresolved ethical question inherent to any such research – and its outcomes – relates to the implications of using neurotechnologies in diagnosis, establishment of medical, social, and legal ontologies, and the impact of such information and constructs on the concept (and value) of personal identity. The psychiatric and neuroethics literature has already become focused on questions of enforced therapy, neuroenhancement, and preventive measures (Matravers 2010; Glannon 2011; Gordijn and Chadwick 2008), and in many ways, this discourse provides the groundwork for consideration of rtfMRI-BCI as discussed here. For example, the issue of how TMS and DBS could affect personal identity has been addressed elsewhere (Jotterand and Giordano 2011), but we assert that it is also worthwhile elaborating upon those deliberations to date and the specific aspects that are most relevant to a discussion of the use of rtfMRI-BCI to assess and treat psychopathy.

Such questions confront contemporary and long-standing notions of self and embodiment and the relation of mind to brain. To approach these questions, we hold that the concept of embodiment is essential to an understanding of how individuals construe their sense of personal identity and/or notion of self. Individuals are shaped by experiences that are interpreted through the medium of the body, which is situated in space and time (Merleau-Ponty 1945). This means that personal identity comprises the aspects of human development and experience that are both biological and psychosocial (Jotterand and Giordano 2011).

It is one thing to establish the importance of embodiment for a definition of personal identity; however, the relationship between the perceptual body (and its instrument for the interpretation of perception, the brain) and the entity referred to as the "mind" still remains unresolved. This issue can be approached from philosophical, neurophysiological, and neuropsychological perspectives and each provide particular insights that putatively describe aspects of the relationship of brain to mind (Churchland 1990; Damasio 1999; Prinz 2005; Heidegger 1962; Jaspers 1949; and Merleau-Ponty 1945). Obviously, we will not settle the question in this chapter; however, we do wish to stress that human experience in the world is defined by bodily sensation and phenomenal cognition (not in a dualistic, Cartesian sense, but rather as a complementary dyad of somatic and psychological reality) (Giordano 2008a; Shook and Giordano 2013), which then prompts important questions about brain interventions that affect mental states. These interventions have the potential to disrupt the integrity of the self, which could be morally questionable in the therapeutic application of neurotechnology if such interventions undermine individuals' autonomy (self-determination) and privacy (protection of health information including the predictive and personal nature of neurobiological information) (Jotterand and Giordano 2011). One problem is that the use of neuroscientific and neurotechnological approaches to "predict" the potential occurrence of a disorder such as psychopathy (that fosters considerable socio-legal concern and consternation) could result in bias(es). As well, using the nature and manifestations of the disorder (i.e., as a potential threat to society) in order to justify interventions without proper consideration of the (integrity of the) personal identity of psychopaths or individuals with psychopathic traits, is ethico-legally problematic.

Assuming, hypothetically, that rtfMRI-BCI technology were to become an established option for treating psychopathy, we predict that social expectations to use such technology would accordingly increase, particularly in light of the recent events of terrorist acts and shootings, and the previously mentioned social pleas for neuroscientific and neurotechnological means of intervention and prevention. Additionally, rtfMRI-BCI might be used to manipulate the brain∼minds of people with psychopathic traits, without the safeguards of appropriate consent. This concern, however, can be quickly dismissed for two ethical and practical reasons. First, the principle of informed consent protects competent subjects (including prison inmates) from frank manipulation and coercion. But let us not be naïve; of course, the potential for coercing inmates may in fact be greater because of their status and background. That said, the principle of equivalence as applied in prison medicine provides a fair measure of surety as it entails (at least in the ideal) that prison populations should receive the same medical care as free individuals, inclusive of the ethical obligation to obtain informed consent. Second, rtfMRI-BCI requires the cooperation of subjects (who want to undergo treatment in order to change their behavior). As previously stated, rtfMRI-BCI uses a type of neurofeedback that demands active participation of subjects in the conditioning process. Coercion and manipulation undermine the quality of therapeutic interventions. Therefore, while ascription to mandatory therapy could offer incentives to criminal psychopaths as conditions for parole, early release or shorter sentencing – if studies show the safety and effectiveness of

rtfMRI-BCI-based interventions – it is paramount to have the full consent of these subjects to achieve the highest degree of effectiveness in the therapy.

Perhaps the real ethical issue is not mandatory treatment of convicted psychopaths, but instead the longitudinal use of (this) neurotechnology. As with certain types of genetic testing (Fulda and Lykens 2006; Hodge 2004), pediatric brain scanning might become mandatory and, depending upon a child's subsequent behavioral development, could be used as a metric to establish thresholds and criteria for pediatric rtfMRI-BCI treatment – as a type of "preventive therapy" or, perhaps more or less accurately, a form of socio-moral neuroenhancement (vide supra). Such treatment would require (substituted) consent of parents but also the assent of a child or young (i.e., less than "legal age") adolescent. Intervention would be presented as a therapeutic good that would enhance the quality of life of the subject, and as a social good that seeks to preserve the safety of the public at large. But we must ask, just how informed could we expect subjects to be, given the nascence and novelty of the technology and the changing epistemic capital of neuroscience? And given these same contingencies, and their influence upon the knowledge base of clinicians, legal practitioners, and/or administrative and political personnel responsible for establishing protocols and precedents, it is important to assess what information is necessary and sufficient to provide to patients about new scientific techniques and technologies and if and how the use (or nonuse) of such approaches is important to clinical equipoise (Giordano 2011a, b). Moreover, given the reliance upon computational informatics (in the comparative evaluation and normative indexing of neuroimaging-based diagnostics; see Giordano 2012d, for overview), we must question how private any information relevant to neurotechnologically based diagnoses and interventions for psychopathy will actually remain (e.g., in the face of possible use of these data for commercial and actuarial purposes) and what burdens, risks, and possible harms such (unintended or in some cases intentional) diffusion of information will incur (i.e., to individuals, communities, and society; Giordano 2011a, b).

The issue of preventive measures raises further questions of whether and in what ways such treatment represents a violation of individual autonomy. In principle, an intervention rendered as enforcement of the law is justifiable only when individuals engage in criminal or socially injurious behaviors (Morse 2010). While common standard of law asserts that absent a determination of guilt, there is no mechanism to (legally) mandate preemptive "treatment," there is a building sentiment – and increasing call (from certain factions of the public, professional and political communities) – for the use of neuroscience and neurotechnology to be employed to "protect the public" that could be used to support arguments for such predictive and preventive approaches. Of course, this stance is contentious, and ongoing debate is focused upon the utility of the spectrum-disorder concept in making predictive inference about future trajectories of bio-psychosocial effects (see, e.g., Giordano and Wurzman 2008; Wurzman and Giordano 2012, for overviews) and representation of the validity, relative value(s), burdens, risks, and harms of this approach in light of outcomes achieved to date. But here we advocate extreme caution; it will be increasingly important to weigh the merit of each type and

application of neuroscientific techniques and technology relative to assessing and "treating" particular conditions, states, and traits in specific individuals. Without doubt, a case-by-case approach should be utilized, but further, it will be important to examine the viability of extant ethical and legal criteria (such as Frye and Daubert standards) and recognize the tendency to use extant technology – and ethico-legal justifications – in ways that are inapt (Giordano 2010, 2012b). It may be that the presence of such neuroscientific techniques and technologies within the legal, economic, and political armamentarium warrants a deeper and more intricate examination, evaluation, and possible reformulation of certain ethico-legal constructs, guidelines, and pre-/proscriptions, and this will constitute something of a sea change (Benedikter and Giordano 2011; Giordano 2011a, b, 2012a–d; Giordano and Benedikter 2010, 2012; Shook and Giordano 2013, in press).

Conclusion

Psychopathy not only affects the individual afflicted but can – and frequently does and will – impact the lives of others: the victims of psychopaths' socially aggressive and violent behaviors as well as their families, friends, and, in many ways, society at large. The challenges posed by the condition, diagnosis, treatment, and prevention of psychopathy to existing constructs of moral agency and criminal responsibility are fortified by the availability and putative viability of ever newer techniques and technologies of neuroscience. The heretofore absence of effective treatments has afforded strong incentives for the development, testing, and implementation of neurotechnologies, such as rtfMRI-BCI, for the assessment and treatment of psychopathy. It may be, as we have noted both in this chapter and elsewhere, that neuroscience and neurotechnology offer real promise and potential to alleviate the individual and social burdens incurred by disease, injury, illness, environments, and age; yet such promise is accompanied by potential problems and perils. In light of this, we have advocated a preparatory stance that is well informed of the practical, ethico-legal, and social benefits, limitations, risks, and implications that neuroscientific and technological progress may offer and incur (Benedikter and Giordano 2011; Giordano 2008b, 2009, 2010, 2012a, b, c, d; Giordano and Benedikter 2011, 2012; Giordano and DuRousseau 2011; Plischke et al. 2012). But a preparatory stance does not necessarily prevent the advancement and use of neuroscientific techniques and technology (Benedikter and Giordano 2012; Giordano et al. 2010); thus, we posit that it will be paramount to determine the ethical and legal criteria with which to evaluate if and what methods and protocols of neurotechnological assessments can be employed to initiate social interventions to mitigate and/or prevent psychopathy and its predisposing traits. This in turn will require establishing thresholds for both diagnosis and any subsequent interventions and, beyond techno-scientific and methodological considerations, will mandate ongoing address, analysis, and revision of existing ethical and legal guidelines that can be engaged to direct and govern the medical, legal, and political use of neuroscience and neurotechnology. We argue that this is both a challenge and opportunity for the field

and practice of neuroethics, not as a stand-alone discipline, but as a critical constituent of a larger infrastructure of medicine, law, and social administration that is responsive and dedicated to individual and public good (Giordano 2010, 2011a; 2011b; Giordano and Olds 2010). It is our hope that this project of neuroethics, legal, and social engagement remains a strongly positive work in progress.

Ethical Implications of Sensory Prostheses

Ethical Implications of Sensory Prostheses

48

Sven Ove Hansson

Contents

Abstract

This survey begins with an overview of currently available and foreseeable sensory prostheses. Cochlear implants are now a routine technology for patients with a dysfunctional inner ear but a functional auditory nerve. Auditory brainstem implants are available for patients whose auditory nerve cannot be used. Visual prosthesis for the blind is a highly active research area but still far from results that can be used in routine clinical practice. Experiments are also made with artificial proprioception and touch for sensory feedback in limb

prostheses. Artificial biosensors are used in pacemakers, and research is being done on implantable drug delivery systems with biosensors that determine dosage. A wide range of ethical issues arise in connection with experiments and clinical usage of sensory prostheses: animal experimentation; informed consent, for instance, in patients with a locked-in syndrome that may be alleviated with a sensory prosthesis; unrealistic expectations of research subjects testing new devices; privacy issues for electronic implants with memory; security issues; effects of sensory improvements on a patient's personality and self-image; cultural effects of the new technologies in disabled communities; and the psychological and social effects of sensory enhancement.

Introduction

Neither the concept of perception nor that of a sense is precisely defined. We tend to use the word "sense" primarily about those of the registration mechanisms in our bodies that give rise to signals reaching our consciousness. This applies to the five classical human senses – sight, hearing, taste, smell, and touch – but also to several other mechanisms that provide us with information about the outside world or about the body itself. Our movements are guided by the sense of balance that is located in the vestibular system of the inner ear and also by proprioception that is based on sensory organs in muscles and joints. Our skin contains temperature receptors for cold and warm, and there are pain receptors both in the skin and on various internal surfaces of the body. We also have "internal senses" that register the body's homeostasis and the status of some of its organs. Chemoreceptors register the concentrations of oxygen, carbon dioxide, and a large number of hormones and other substances. Some of these registrations produce conscious sensations; for instance, receptors sensitive to insulin and nutrients in the blood have an influence on hunger. However, most of the chemoreceptors operate on an unconscious level. Here, the term "sense" will be used in a broad sense that covers sensors and receptors whose signals seldom if ever reach consciousness.

Artificial devices that improve, replace, or supplement our senses differ in the degrees to which they are integrated into the body. A magnifying glass is used to improve sight and a blind person's stick to partly replace it. We think of these as tools. Sense-enhancing tools such as eyeglasses and hearing aids that are worn for long periods of time are often referred to as assistive technologies. Assistive devices are called prostheses if they replace a body part and implants if they are operated into the body. Here, the focus will be on devices that are integrated with the body to a high degree, mainly prostheses and implants.

The purpose of this chapter is to provide an overview over sensory reconstructions and enhancements and the ethical issues that they give rise to. Paragraph 2 summarizes the status of current technology and technological development. Paragraph 3 introduces the major ethical issues that these technologies tend to give rise to. The chapter is followed by three others that provide in-depth discussions of the

most discussed ethical issues in this field, namely, cochlear implants (▶ Chaps. 49, "Ethical Issues in Auditory Prostheses"; ▶ 50, "Ethical Issues in Cochlear Implantation") and sensory enhancement (▶ Chap. 51, "Sensory Enhancement").

Currently Available and Foreseeable Devices

Hearing

Hearing aids in the form of ear trumpets have been used since the seventeenth century. Wearable electronic hearing aids have been available since the early twentieth century, and their development was a driving force in the early stages of electronic miniaturization (Mills 2011). However, hearing aids can only be used by persons whose hearing loss is not complete. A large technological step forward was taken with the introduction of cochlear implants. These are sound-activated devices that directly stimulate the auditory nerve, thereby bypassing dysfunctional parts of the inner ear. The first experiments with cochlear implants were made in the late 1950s, and they have been used clinically since the 1980s. Cochlear implants give rise to a sense of hearing that is sufficient for understanding speech. The best results are obtained when a deaf child receives the implants before 2 years of age (Peterson et al. 2010).

More recently, auditory brainstem implants have been developed for use in patients with a nonfunctional auditory nerve. The technology is largely the same, the major difference being the placement of the implant (Schwartz et al. 2008).

Seeing

Prosthetic vision for the blind ("bionic eyes") is a major research area in medical technology. The basic construction principle is the same as for cochlear implants, namely, that stimuli from technological sensors are relayed to the nervous system via a nerve-implant interface. The potential sites for implantation follow the nerve pathway that takes visual impressions to the brain: the retina, the optic nerve, the lateral geniculate nucleus, and the visual cortex (Rizzo et al. 2007). Retinal prostheses have the advantages of requiring less complicated surgery than the other options. They also make use of the natural processing system for preparing visual information before it reaches the cortex. However, the retina can only be used as an implant site in patients who have a large number of intact retinal ganglion cells (the cells that transmit visual impulses to the brain). Therefore, one of the other implant sites will have to be used, for instance, in patients with glaucoma or diabetic retinopathy (Fernandez and Hoffmann 2011).

Research on visual prostheses has been conducted since the 1960s (Rizzo et al. 2007). In 2011 there were about 23 devices under development, and five different research groups performed clinical trials with retinal implantation (Fernandez and Hoffmann 2011). A typical bionic eye consists of one implanted

and one external part. The implanted part is placed in the eyeball. The external part includes a small camera that is mounted on eyeglasses and a battery carried elsewhere on the body. Signals from the camera are sent wirelessly to the implant, where they are distributed to up to 60 electrodes placed on the retina, for instance, in a 6×10 array (Humayun et al. 2012).

Thus far, the results from retinal implants are much less impressive than those obtained with cochlear implants. Blind people obtain a black and white, coarse-grained "pixelated" impression of the environment. In the most successful cases, they can recognize a large letter or track a moving dot on a computer screen (Sample 2013). The usefulness of presently available bionic eyes to improve the quality of life has not yet been fully demonstrated (Fernandez and Hoffmann 2011).

Taste and Smell

Technologies are available that partially imitate human olfaction and taste ("electronic noses" and "electronic tongues"). However, currently this work has its focus on external measurement instruments (Wilson and Baietto 2009). Implantable devices seem to be rather far away from realization.

Proprioception and Touch in Limbs

Previously, limb prostheses were simple constructions like a wooden leg, and their function was primarily cosmetic and/or supportive. Today, myoelectric prostheses are being built that contain motors directly operated by the patient through connections with the nervous systems (Micera 2010). In order for these prostheses to function properly, sensory feedback is needed. Two types of sensors have been developed for such feedback, corresponding to touch respectively proprioception. Accelerometers have turned out to provide a useful mechanism for proprioception although they operate in a quite different way than natural proprioception. Accelerometer technology has also been developed for gait rehabilitation in hemiparetic patients. In the latter case, wearable accelerometers provide feedback to the patient, for instance, through sounds (LeMoyne et al. 2009).

In hand prostheses, touch sensors are used in combination with artificial proprioception. Both types of sensors can be connected either to a cortical implant or to nerves in the stump. It has been proposed that in the latter case sensory signals from the prosthesis can be connected to the remaining nerves in a way that corresponds to the patient's "phantom" sensations from the lost limb (Kroeker 2011).

The ultimate goal of connecting sensors in a limb prosthesis to the nervous system is to obtain a motor-sensory feedback loop similar to that of natural limbs. However, the difficulties in achieving this are tremendous, and despite considerable progress the functionality of currently available prostheses is still rather limited (Micera 2010).

Biomonitoring

A large number of research projects aim at the introduction of biosensors into the body in order to replace or supplement the body's own sensors. Such sensors may, for instance, continuously record electric signals in the brain or in the heart in order to detect dangerous events in these organs. They can also be used to follow pulse, blood pressure, intraocular pressure, or other physiological parameters. Sensors that measure bladder fullness can help patients with spinal cord injury to regain bladder control (Chew et al. 2013). Much of the research has been devoted to chemical sensors that register chemical health indicators such as the concentration of glucose and other metabolites, hormones, or drugs in the bloodstream or in specific organs (De Venuto and Vincentelli 2013; Vaddirajua et al. 2010).

Biomonitoring can be used either as a decision aid or as part of automatic feedback systems. As decision aids they provide the opportunity to follow diagnostic parameters continuously on all days. In addition they make it possible to collect diagnostic data at a distance. By holding, for instance, a mobile phone over the implant, the patient can transfer the data and send it to the clinic (Bauer 2007).

The use of biosensors in automatic feedback systems opens up new therapeutic prospects. Dynamic artificial pacemakers are already in widespread clinical use. They adjust the heart rate to physiological parameters, in a way intended to mimic the normal regulation of the heartbeat. The same technology can be used in mechanical circulatory support devices (left ventricle assist devices) and in future artificial hearts. Implantable cardioverter-defibrillators (ICDs) detect cardiac arrhythmia and correct it automatically by emitting an electric pulse (Puri et al. 2013).

Much research is conducted on using chemical sensors as parts of implanted drug delivery devices. This technology has the advantage of allowing for more precise and timely dosing. Furthermore, if the drug is delivered to the specific site where it is needed, higher local doses can be used with less systemic side effects than if the drug is distributed through ingestion or intravenous injection. In other words, this technology can shift the balance between therapeutic and adverse effects in a favorable direction.

Diabetes management is a particularly interesting application for implantable biosensors. Implanted glucose sensors can potentially improve the patient's monitoring of her disease, thereby improving insulin dosage. Future artificial pancreases will have to be connected to sensors that regulate insulin release (Srivastava et al. 2011). However, due to the body's reactions to implanted objects, it has turned out to be extremely difficult to construct glucose sensors that function reliably more than a week or so after the implantation. Inflammation and foreign body responses are still a major obstacle in the development of biosensors (Vaddirajua et al. 2010).

Enhancement and New Senses

Some of the technologies that have been developed for sensory prostheses can also be used for the sensory enhancement, i.e., they can make it possible to perceive

signals that a normal human being cannot perceive: infrared or ultraviolet light, ultrasound, infrasound, magnetic fields, or chemicals that are odorless for a normal human. Most such enhancements are far away from technical realization, but some low-tech enhancement technologies are already in use in the biohacking and body modification subcultures.

Probably the most common such implants are subdermal magnets, i.e., small silicon-coated magnets that are introduced permanently under the skin, usually on finger pads. Implanted magnets make it possible to feel certain electromagnetic fields, and some persons with these implants report that they can feel whether certain security alarms are on or off. The operation is offered commercially by some body modification practitioners, and reportedly thousands of people already have implanted magnets (Hameed et al. 2010; Firger 2013). Other types of sensors have been implanted in single individuals. For example, one person had a “third eye” in the form of a camera attached to implants at the back of his head. The camera took a photo every 60 s that was published on a website (Parry 2011). Another member of the body modification movement has a fairly large electronic device implanted under the skin of his forearm. Its function is to continuously record his body temperature and store this data (Woollaston 2013). An implantable compass is under development (Firger 2013).

Ethical Aspects

With the exception of cochlear implants, therapeutic sensory prostheses have not been subject to much ethical discussion. This may be because the purpose of such devices appears to be ethically unproblematic. But close inspection will show that quite a few ethical concerns need to be taken into account. Several of these concerns are common to the different types of sensory prostheses.

Animal Experiments

Like many other medical innovations, new implants are tested on animals before being tried out on humans. Animal experiments are ethically problematic, even when performed to avoid even more problematic testing on humans. It is generally agreed that the use of animals with higher taxonomical classification, in particular primates, should be avoided as far as possible. However, the function of implants in the nervous system is often difficult to test on the lower species, and therefore monkeys have often been used in these experiments. It is particularly important in such experiments to apply the so-called 3 Rs (Russell et al. 1959): replacement by nonanimal experiments as far as possible, for instance, through efficient use of simulation methods; reduction of the number of animals; and refinement by careful veterinary attention to reduce pain and distress (Sughrue et al. 2009; Gerrek 2009; Nobis 2009).

Informed Consent and Professional Responsibility

The implantation of sensory devices requires the informed consent of the patient. In some cases, informed consent may be difficult to obtain, or its quality can be questioned. This applies to people who are unable to communicate, for instance, due to a locked-in syndrome that may be alleviated with a sensory prosthesis. Another problem is that a patient's willingness to have an implant may be driven by unrealistic hopes about its efficiency. Since informed consent requires that the patient has understood the information, it may be questionable in such cases whether the patient's consent is fully informed. This seems to be a particularly serious problem in trials with bionic eyes. Due to the rudimentariness of the perception obtained with this technology, very few of the eligible patients are willing to volunteer as experimental subjects in implant trials. The few who volunteer tend to have unrealistic hopes about the outcome, hopes that cannot be fulfilled with the present technology (Xia and Ren 2013). It is essential that potential participants in trials with these and other sensory improvement technologies are sufficiently well informed and that they have a realistic understanding of the expected effects of the intervention.

According to the standard view in medical ethics, informed consent (when obtainable) is a necessary but not a sufficient condition for an intervention to be ethically acceptable. A reasonably favorable risk-benefit assessment is an independent ethical requirement and a sine qua non for an intervention to be acceptable. It is a violation of medical ethics to perform an intervention that does harm to the patient (without outweighing medical benefits), even if the patient consents to it and perhaps entreatingly asks for it. This is a pertinent issue not only in scientific experiments with sensory prostheses but also in relation to some of the body modifications undertaken by biohackers.

The abovementioned implantation of temperature-recording device into the body of a biohacker provides a clear example. No physician was willing to perform the surgery, presumably due to the potential risks involved in such an operation. Instead it was performed by a "flesh engineer" (Woollaston 2013). This raises an important ethical issue. If it would be unethical for a surgeon to perform an operation due to its high risks, can it be ethical for someone else such as a "flesh engineer" to perform it? This is part of a much larger issue, namely, whether the ethics of a profession such as the medical profession should be seen as the ethics of a particular class of activities or as the ethics of a particular class of persons. According to the former interpretation, the "flesh engineer's" operation would qualify as at least as unethical as the same operation hypothetically performed by a qualified surgeon. (Probably it should, under this assumption, be seen as even more unethical since lack of equipment and competence made it more risky than if a surgeon had performed it.)

Privacy and Security

The continuous monitoring of health-related parameters that is possible with implanted biosensors has an obvious and important advantage: It can be used to improve treatment. However, some of the information that is obtainable in this way

may be privacy sensitive, for instance, information about concentrations of alcohol, cotinine (a biomarker for tobacco exposure), or other substances related to recreational drug use or to compliance with lifestyle recommendations. Future multifunctional sensors can make such monitoring possible without the patient's knowledge or consent. Such monitoring could potentially lead to decisions contrary to the patient's interests, for instance, concerning eligibility for insurance.

There is also a risk of unauthorized access to information from implanted biosensors. Scannable implants can be read without the patient's consent, or the information contained from them can be intercepted when sent electronically from the patient to the healthcare provider (Bauer 2007; Bramstedt 2005). Like other digitized information, the information recorded in sensory devices can easily be stored. An electronic eye might, for instance, be provided with a memory function that saves everything it records. This may threaten the privacy of persons within camera reach of the person who carries the implant. When the implant carrier dies, the recorded data is still there and could potentially be archived against the person's wish.

In some cases it can be medically motivated to combine implanted biosensors with a geographical tracking unit (GPS receiver). If a biosensor detects a serious cardiac event or a severe hypoglycemia in a diabetic, an alarm signal to an emergency medical service, including the patient's geographical position, may save her life. But on the other hand, an implanted geographical tracking unit can be perceived as a serious infringement of privacy. It has been argued that the connection of implantable devices to external electronic communication networks may have large effects on how we see the relationship between the human body and its social and technological environment. Thus, "as we transform the human body internally with microchips and biosensors, we also transform externally how individuals interact and live in the world" (Bauer 2007).

The security of pacemakers, defibrillators, drug delivery devices, and other potentially lifesaving implants against unauthorized interventions is a serious matter that has not received sufficient attention. These devices can often be reprogrammed wirelessly, which is of course convenient in the clinic. However, some such devices are susceptible to reprogramming attacks that are performed with the intent to injure the patient (Halperin et al. 2008).

Effects on Personality and Self-Image

An individual's personality depends in part on her bodily experiences. New sensory experiences can potentially have effects on her personality and self-image. Although very little is known about such effects, the development of more efficient artificial biosensors gives us reason to watch out vigilantly for them. What effects can visual stimuli from a bionic eye have on a person with no previous experience of visual stimuli? What will the effects be of continuous exposure to new types of perceptual information, such as ultrasound or infrared light? Is there a risk of mental overload, or will there be personality changes?

There has been considerable debate about the phenomenological nature of the experiences obtained through sensory substitution, for instance, when "visual" information is mediated to a blind person through tactile stimuli. According to the so-called deference thesis, the experiences of such stimuli are visual in nature. According to the dominance thesis, these experiences remain within the tactile realm (De Preester 2011). Some authors have argued in favor of a third position, namely, that these sensations belong to a new category that can be subsumed under neither the replaced nor the replacing sensory modality (Farina 2013). This third position may be particularly plausible when the replacing sensory impressions are of an entirely new type, for instance, sensations obtained with electrical stimulation of the cortex. Although usually not discussed in ethical terms, the nature of "new" sensory modalities has ethical implications. The introduction of entirely new modes of perception would seem to increase the need for carefully following the psychological effects on the persons receiving these types of sensory impressions.

It is usually assumed that in order to be successful, a prosthesis has to be perceived by the patient as a part of her own body. However, in many cases the prosthesis has instead been perceived as a foreign object. Much can be learned from the experience of hand transplants. The recipient of the first hand transplant never accepted the new hand, and after 2 years he asked to have it amputated. Other patients have accepted a new hand but only after 4–5 months when sensation had been regained (Swindell 2007; Dickenson and Widdershoven 2001). Trials with artificial hands confirm the importance of the sensory component of advanced limb prostheses. The chances for a prosthesis to be effectively used and to be perceived as part of one's own body seem to increase with the introduction of realistic sensory feedback (Micera 2010).

Social and Cultural Effects

Medical interventions, including prostheses and implants, have effects not only on the individuals on which they are performed but also on social groups and on society as a whole. Radical improvements in treatment options will change the situation of disabled subcommunities in our societies. However, not all therapeutic improvements have been received positively in these subcommunities. The "fat is beautiful" movement denies that obesity is a disease requiring treatment and medical attention. Segments of the dwarf community have reacted against the introduction of therapies against their condition, seeing this as a threat to the future existence of their way of life and their organizations (Berreby 1996). By far the strongest such counterreaction is that of a part of the Deaf World against cochlear implant surgery in prelingually deaf children.

The criticism of cochlear implantation is strongly connected to a positive view of deafness in the Deaf World. Some of its members deny that they have an impairment or disability. Instead, they view themselves as members of a minority culture with its own language, customs, attitudes, knowledge, and values. Widespread use of cochlear implants will lead to a drastic decline in the population of this minority

culture. Deaf activist have often referred to the ethical principle that minority cultures should be preserved. They claim that large-scale implantation of children conflicts with the right of the deaf language and cultural minority to exist and flourish. The term "genocide" has sometimes been used to describe that prospect (Lane and Bahan 1998). This claim has given rise to an interesting discussion about the definition of a minority culture and whether cultures have intrinsic value (Levy 2002). Critics have pointed out the problematic nature of arguments that give precedence to the preservation of a culture over the interests of individual children. Some have noted that it is difficult to draw the line if cochlear implants are disallowed for this reason. If cochlear implants are unethical, then how should we judge the rubella vaccine (Balkany et al. 1996)? In clinical medicine, cochlear implants are commonly seen as an adequate treatment of deaf children, contrary to the Deaf World view just referred to. The reader is referred to the chapters authored by Thomas McCormick and the one from Linda and Paul Komesaroff for two nuanced views on this controversy, one with its roots in the medical community and the other in the Deaf World. (See also Clausen 2009.)

Enhancement may give rise to additional issues related to cultures and subcultures. It is not inconceivable that persons who have received certain enhancing interventions may come to form new subcultures. Furthermore, enhancement may change our views of normality, so that some of the unenhanced may come to be seen as "subnormal" in the relevant respect. If some people submit to enhancement, others may feel a pressure to follow suit, for the same reason that athletes who use performance-enhancing drugs induce others to do the same.

Some of the personal characteristics that can be enhanced through implantation or other interventions seem to have a function similar to that of positional (economic) goods, i.e., goods that give their owner a place in the social hierarchy. As an example of the latter category, having a color TV at the time when this was a new and exciting technology contributed positively to the owner's social status. This effect decreased in importance as color TVs became common. Access to a particular type of positional goods typically increases with economic growth, and it can then lose its positional value and be replaced by other objects as markers of social status. Personal characteristics with similar properties as positional goods may be called positional characteristics. Height is an example. If some of those predisposed to short stature are treated, the relative position of those untreated or untreatable can be expected to worsen. Experience from cosmetic surgery corroborates this mechanism. Our concepts of normal looks have changed when enhancing technologies became available. Hence, buckteeth were more accepted 50 years ago when orthodontic treatment was not available. The introduction of breast implants has had similar effects, and surgery that erases certain facial features has the same potential (Goering 2003).

Generally speaking, enhancement of a positional characteristic can have negative effects in the long run on the social situation of untreated individuals. Therefore, a proactive discussion is needed of distributive and procedural justice in relation to such enhancements. Cognitive and sensory capacities are examples of characteristics that may be positional.

On the other hand it must be conceded that progress is often hard to achieve unless some humans are allowed to go forward before others. At the bottom line, the enhancement issue is about what kinds of human beings there should be. Should future people be stronger and more intelligent than we are, and should they be able to directly perceive features of the environment that are inaccessible to us? Issues about what kind(s) of persons there should be are among the most difficult ones to deal with rationally in moral philosophy (Clausen 2008). The very basis for the discussion is insecure. What criteria should we use? Should we judge future persons by our own criteria or by the criteria that we predict (and partly determine) them to have? Possibly, the best way to tackle issues of enhancement is to do it incrementally, i.e., deal with each issue when it arises rather than trying to develop general principles that cover all potential future interventions in the human body.

Conclusion and Future Directions

We are probably only at a very early stage in the development of sensory prostheses. The experience so far gives us reason to believe that sensory prostheses can contribute substantially to people's quality of life, but we have also seen that the introduction of sensory prostheses can have negative psychological and social effects. Since the issues are largely similar for different types of sensory prostheses, we need to combine the rather fragmented ethical discussions on the different types into a more general, proactive discussion on the future of artificial sensory devices.

Ethical Issues in Auditory Prostheses

49

Thomas R. McCormick

Contents

Abstract

The innovation of cochlear implants and other auditory prostheses designed to improve hearing and oral communication for deaf and profoundly hard-of-hearing individuals is relatively new. Although such devices open the possibility of hearing, their use as a clinical treatment first for adults and later for children has been accompanied by a number of ethical conflicts and controversies. Compassionate physicians began to use this invention in both adults and children before scientific testing could be carried out to measure the risks and benefits of the new treatment. Controversy swirled around questions of the most appropriate age to implant cochlear devices in children. Early devices were extremely limited, and there were notable instances of device failure. The cost of this technology raised issues of cost containment in an era of scarce resources. The relatively rapid rise in the use of a treatment that allows deaf persons to hear has had a dramatic impact upon the Deaf community whose members fear a radical reduction in Deaf members, leading to

a diminished community, fewer people using American Sign Language (ASL), and the loss of resources that have traditionally been available to promote processes of education and enhancement for those unable to hear. The judicious application of ethical principles offers promise in identifying ethically acceptable options toward resolving these issues. Ethical principles of beneficence and nonmaleficence require that we carefully examine issues of risk and benefit for patients. The principle of autonomy underscores the importance of informed consent and informs us of the duties of surrogates when deciding for minor children. Respecting diverse values within a pluralistic society places a strong emphasis on exercising principles of justice and fairness.

Introduction

A prosthesis is considered to be an artificial device used to replace a missing body part such as a limb, a heart valve or, to assist the functioning of an impaired organ. It is widely held that one's natural organs and limbs are superior to any synthetic replacement. Therefore, readers must have been startled at the title of a *Scientific American* article, asking "Should Oscar Pistorius's Prosthetic Legs Disqualify Him from the Olympics?" (Eveleth 2012). It was held by some that Oscar's prosthetic legs gave him an unfair advantage over other runners with two normal legs. Oscar suffered bilateral leg amputations as a child, and as an adult, began running with prosthetic legs called "Cheetahs." He was so successful in the Special Olympics that he decided to try out for the Olympics. In this context, a controversy broke out over possible advantages Oscar might enjoy by running with the prosthetic legs and feet. Eventually, Oscar was allowed to compete in the 2012 Olympics and ran hard, but did not win a medal. Still, many gained a new awareness that prosthetic legs and feet have undergone almost unimagined improvements in recent years. Similarly, improvements continue in the field of auditory prostheses. Today's cochlear implants are a vast improvement over the initial device implanted in the mid-1980s, and new types of implements, such as the hybrid, are currently in the testing stages. This chapter explores ethical issues related to the advent and use of auditory prostheses.

When it comes to auditory prostheses, even with major improvements, no one has yet made the argument that these synthetic devices are superior, or even nearly as good as the natural organs for hearing. However, there is a sense of amazement that after centuries of human existence in which little could be done to allow or enhance hearing for the deaf and the profoundly hard of hearing, great strides have been made in just the past few decades through the invention of hearing-aids and cochlear implants. These innovative devices, along with other inventions such as the auditory brainstem implant and vestibular-cochlear prosthesis, offer new hope for deaf individuals who are desirous of hearing and speaking as opposed to communicating primarily through American Sign Language (ASL).

Brief History of Deafness and Society's Responses

It is theorized that a small minority of persons were deaf from the earliest history of humankind. Deaf individuals were mentioned in ancient Jewish literature, and their special needs were recognized within that caring community. In Gannon's *Deaf Heritage*, several early historical references are made concerning deaf persons. In 355 BCE, Aristotle claimed that those "born deaf become senseless and incapable of reason" (Gannon 1981). Aristotle also claimed, "Men that are deaf are in all cases dumb; that is they can make vocal sounds, but they cannot speak" (Gannon 1981). Of course, we know today that Aristotle thought wrongly, having based his statements on his limited personal observations. Nearly 1,000 years later, in 721 AD, St. Bede wrote about St. John of Beverly teaching a deaf-mute to speak, a notable achievement (Gannon 1981). Rudolphus Agricola (1443–1485) writes about a deaf-mute who learned to read and write. Girolamo Cardano (1501–1576) is the first physician of record to recognize the ability of the deaf to reason (Gannon 1981). In 1661, two deaf persons, Matthew Pratt and Sarah Hunt, married in Weymouth, Massachusetts. Cotton Mather claimed that Sarah "spoke with Signs" and that her children learned to speak "sooner with eyes and hands than by their lips" (Lang 2007). Benjamin Franklin and John Quincy Adams were notable Americans who became aware of pioneering efforts to educate the deaf in the eighteenth century. In 1784, when Adams was ambassador to France, he sent a letter to William Cranch of Cambridge, Massachusetts, describing his impressions of the school in Paris of Abbe Charles-Michel de l'Epee. Adams wrote that Epee taught deaf pupils "not only to converse with each other by signs, but to read and write, and comprehend the most abstracted metaphysical ideas" (Lang 2007). In short, from earliest times, there have been references to the deaf and a gradual, growing appreciation in the hearing community for their capabilities. Anecdotally, deaf persons used hand-signs from earliest times, using simple, intuitive gestures to communicate their needs to others. In the 1500s, in Europe, sign language began to be organized as a formal communication system (Naff 2010). Deaf persons married, raised families, owned property, and functioned effectively in society.

In contrast to Aristotle's notions, as it became more widely accepted that deaf persons were indeed intelligent and capable of reasoning, more and more efforts to provide education of the deaf were undertaken and new means were utilized to assist those without hearing to communicate. Schools for the deaf sprang up in several countries. France had a school for the deaf. After studying techniques in educating the deaf in France, in "1816 Laurent Clerc, a deaf teacher of the deaf, and Thomas H. Gallaudet, a minister, traveled to the United States where they established the Connecticut Asylum for the Education and Instruction of Deaf and Dumb Persons, the first permanent school for the deaf in America, opened in Hartford "on April 15, 1817" (Crouch 2002). Their efforts contributed greatly to the spread of what would soon be known as American Sign Language (ASL). In 1864, Gallaudet's son, aided by Clerc and colleagues, established the Columbia Institute

for the Deaf in Washington D.C., which has since been renamed Gallaudet University and has served as an important institution of higher education for deaf persons (Naff 2010).

In the early years of deaf education, controversy arose over the most effective ways to teach methods of communication to deaf people. The oralists and the manualists represented two different ideas about communication. The oralists believed the deaf should be taught to speak and to lip-read. The manualists believed that deaf persons should be taught sign language. Alexander Graham Bell, inventor of the telephone, whose wife was deaf, believed strongly that learning to speak and to lip-read were important so that deaf persons could live and work within the majority hearing society. Others had far greater confidence in signing as a way for deaf persons to communicate. Gradually, a Deaf culture emerged and deaf persons who identified with the Deaf culture argued that deaf persons will never hear or speak like the hearing and so should abandon efforts to do so and become proficient in sign language. The debate continues to this day and as will be shown later on in this chapter, and as well in (▶ Chap. 50, "Ethical Issues in Cochlear Implantation") and gives rise to some of the ethical issues in the use of auditory prostheses.

In the last century, a number of assistive devices have come onto the market and many hearing-impaired individuals use these external assistive devices in their daily lives. Deaf and hard-of-hearing individuals can communicate by telephone using telecommunications device for the deaf (TDD). A hearing-impaired person can also communicate over the phone with a hearing person via a human translator. The use of internet, email, and mobile phone text-messaging are beginning to take over the role of the TDD. Software programs are now available that automatically generate a closed-captioning of conversations. Examples include discussions in conference rooms, classroom lectures, and religious services. Skype and similar video technologies can be used for distance communication using sign language. Video-conferencing technologies permit signed conversations as well as permitting a sign language English interpreter to voice and sign conversations between a hearing-impaired person and that person's hearing party. Other assistive devices include the use of flashing lights to signal events such as a ringing telephone, a doorbell, or a fire alarm. Hearing-dogs are a specific type of assistance dogs specifically selected and trained to assist the deaf and hearing-impaired by alerting their handler to important sounds, such as doorbells, smoke alarms, ringing telephones, or alarm clocks.

Hearing-aids have become more powerful and offer enhanced hearing to some who maintain a residual ability to hear sounds. Over 1,000 different models are available in the United States although they all include a microphone to pick up sound, an amplifier to boost sound, a speaker to deliver sound to the ear, and a battery power source. Over 65 % of users employ binaural hearing-aids. It is estimated that there are 28 million Americans who have "ski-slope" loss in which their ability to hear high-pitched sounds plummets radically (Nuzzo 2010). These patients are likely candidates for a newer "hybrid" cochlear implant that is currently being tested.

The Cochlear Implant

Without a doubt, the most notable innovation has been the invention and development of the cochlear implant device. The cochlear device has several parts, using an external microphone to pick up sounds from the environment and send them to a receiver implanted under the skin behind the ear which relays these to an array that has been carefully placed inside the cochlea. Signals from an array of about 22 electrodes are sent to the auditory nerve and then to the brain. With practice and assistance from an audiologist, the deaf person with a cochlear implant can learn to recognize the sounds of speech and can more successfully pick up spoken language, usually with the assistance of a speech therapist in the early stages as the brain is adapting to perception of sounds. Cochlear implant recipients often augment hearing by lip-reading. Cochlear implants are described by Hansson as a new and important class of implants interfacing with neural tissue to treat deafness (Hansson 2005). Graeme Clark, inventor-developer of the multiple channel electrode array, claims this prosthetic innovation is the first major device since sign language was developed over 200 years ago to assist profoundly deaf people in hearing speech and other sounds, enabling them to communicate more freely (Clark 2003).

On February 25, 1957, Dr. Andre Djourno and Dr. Charles Eyries, in France, were the first surgeons to implant a single electrode in the cochlea of a patient. Due to a prior surgery to remove large bilateral cholesteatomas, this 57-year-old male was left deaf and with facial paralysis. The primary purpose of the surgery was to provide a right-side facial nerve graft using fetal sciatic nerve tissue. Djourno had been experimenting with nerve-stimulating devices and suggested that since the site was exposed, there was little to be lost by implanting an electrode in the cochlea, and Eyries, the surgeon, agreed and both surgeries were carried out. Apparently, the nerve graft worked, and as well, the electrode allowed the patient to hear rudimentary sounds (Eisen 2006).

In the late 1960s, in the United States, Dr. William House worked with Jack Urban, a skilled engineer who had developed some excellent new neurotologic medical instruments. By this time, there was evidence that synthetic materials, such as pacemakers, could safely be implanted in the human body. Once reassured about this safety issue, House and Urban turned to the issue of efficacy. One patient in particular, Charles Graser, who had been deaf for 10 years from ototoxicity, was a willing subject for their experiments. They further developed the single-electrode implant and teamed with 3 M to manufacture these (called the House/3 M cochlear implant) in the United States in the 1970s (Eisen 2006).

Other pioneers in developing the cochlear implant were Robin Michelson, an otolaryngologist, and Michael Merzenich, a neurophysiologist, brought together as a team by Francis Sooy, chairman of a small Department of Otolaryngology at University of California, San Francisco (UCSF). Their work determined that in order to convey complex sounds such as speech, a multiple electrode array would be necessary (Merzenich 1973). The race to develop a multiple electrode array was inspired by the presentation of their work at the American Otological Society meeting in 1973.

In 1974, the NIH took the lead in requesting an objective assessment of the progress in cochlear implants. The contract was awarded to Robert Bilger and his team from the University of Pittsburgh. Thirteen subjects with cochlear implants were flown to Pittsburgh. Testing demonstrated that the single-channel electrode did not allow subjects to understand speech. However, it did help lip-reading, improved quality of life, and significantly helped the speech production of the subjects. Although the implantation of single electrodes was soon to come to an end, the Bilger Report, showing objective benefits and minimal risk, actually opened the door for funding research into a multiple channel device (Eisen 2006). Several thousand patients had been implanted with single-electrode devices by 1984, when the Food and Drug (FDA) granted formal approval of the device. It is clear that the clinical application of these implants prior to thorough studies on the risks and benefits of the new device and prior to FDA approval contributed to the ethical controversy of the time.

In about the same time period, Graeme Clark was experimenting with the development of a multielectrode cochlear implant. He hypothesized about the limitations of the single electrode as early as 1969 in his graduate thesis at the University of Melbourne (Clark 1969). Clark worked on developing all of the components for a multi electrode array. He implanted his device in an adult patient in 1978. As described by Lantos, "Multichannel devices divide the incoming signal into various frequency bands that are then transmitted to various sites of stimulation spanning the inner ear. Low-pitch sounds are sent to one part of the cochlea, high-pitch sounds to another, more closely mimicking the human ear. Because multiple channels provide a more detailed representation of sound, they are thought to allow better speech understanding than do single-channel devices. Clarke's device was approved in 1985" (Lantos 2012). Note, that although the FDA had not yet given approval for the use of CI in children, they were nevertheless used in the clinical context as therapy for deaf children. Many, particularly in the Deaf community, believed such applications to be unethical in the absence of clinical trials demonstrating their safety and efficacy in children. Finally, in 1990, the FDA approved the use of cochlear implants in children aged 2 and over (Institutes of Health 1990).

Ethical Issues

The FDA's decision to allow implants in children as young as 2 years had the effect of throwing fuel on the fires of controversy. Emotions flared and members of the Deaf community claimed that allowing cochlear implants in young children was an extreme threat to Deaf Culture (Lantos 2012). The following year, 1991, spokespersons for the National Association of the Deaf (NAD) issued a statement deploring the FDA's decision. They argued that cochlear implants in children were experimental, and studies had not been done to produce good evidence of usefulness. They noted that the FDA did not consult with experts on deafness and deaf education and that the value and benefits of sign language had not been fully considered. They claimed that the psycho-social development of deaf children

had not been fully considered. They demanded that surgeons discontinue implanting children until studies were completed. Most controversial was the claim of NAD that deafness “comprises a linguistic and cultural minority” and their protest that children should not be subjects of biological engineering that would change them from being a full member of a minority community and result in membership in the majority community. In addition, NAD recommended a national conference to address ethical issues surrounding cochlear implants in children (NAD 1991).

In response, a conference was convened at National Institutes of Health (NIH) in 1995, but it was not the conference that NAD had intended. The NAD wanted the conference to address the broad spectrum of ethical issues in cochlear implant. Instead of addressing these ethical issues, the conference had a more narrow focus on new innovations in cochlear devices and implant surgery and new information about the efficacy of such interventions in deaf persons. Although the conference was multidisciplinary in nature with representatives from otolaryngology, audiology, speech-language pathology, pediatrics, psychology, and education, and included a public representative, “there was no representative from Deaf culture” (Lantos 2012). Whether an oversight, or intended, an opportunity was lost for rapprochement.

The 1990s was tumultuous with both sides in the controversy seeming to dig-in to established positions. The Deaf culture claimed that not enough study had gone into examining and analyzing the efficacy of cochlear implants and that innovation and technology had unduly charmed the public into believing something as yet unproven. Some in the Deaf culture interpreted the use of cochlear implants as a direct assault on their Deaf community with the intent of minimizing the ranks of people communicating in sign language and “mainstreaming” more and more deaf individuals – thus reducing the population of the Deaf culture.

On the other side, many in the health care community felt that an innovative treatment that could help deaf persons hear, learn to speak fluent English, and improve their situation in life in terms of education, employment, and social relationships was being prohibited by the NAD for the sake of its own members. They argued that 95 % of deaf children are born to hearing parents who want their deaf children to hear with the assistance of the cochlear implant and to speak and participate in their family and community (McCormick 2010).

Just when it seemed this controversy was at a stand-off, there was a shift, primarily coming from the Deaf community and NAD. A new position paper was drawn up by NAD in 2000 that softened its earlier opposition and for the first time recognized cochlear implants as one of several options that were available to deaf persons. It encouraged parents to study the many diverse options open to themselves and their deaf infants, including information about ASL and the deaf community, so that they could render “informed consent” in a meaningful way when it became time to choose a treatment option (NAD Cochlear Implant Committee 2000).

Ethical issues continue. Current ethical issues include concerns over the safety and efficacy of cochlear implants, and whether sufficient research has been done to

provide scientific evidence of proportional benefit to those implanted with the cochlear device. Additionally, there is ethical controversy over the issue of device failure and the identification of faulty devices and whether they should be removed and replaced and if so, who should pay for such procedures? Controversy continues over the optimal age in children for cochlear implant. Since parents are surrogate decision-makers for minor children, how can decisions be formed that are in the "best interests" of the affected children when parents have beliefs that may delay or prohibit cochlear implant? In such cases, should health care professionals abandon the ethics of consensus-building and resort to force, for example, by notifying Child Protective Services (CPS) of possible medical neglect and asking the courts to intervene on behalf of minor children by mandating a cochlear implant? What about deaf parents who have deaf children and want their deaf child to learn ASL and to become a participating member of the Deaf community, how do we balance the duty of "respect" for a family's unique value system and our duty of "beneficence" to a dependent, minor child? On the other hand, some deaf patients have found their cochlear implant is sufficiently helpful that they now desire a second implant to provide bilateral hearing. In an era of scarce resources, should there be policies that encourage or restrict payment for bilateral cochlear implants?

Informed consent is a fundamental ethical principle in modern health care, stemming from the more basic principles of respect for persons and respect for patient's autonomy. Obtaining informed consent from a patient is a dynamic process. First, the patient must be competent and possess decisional capacity. Full information pertaining to any medical intervention must be communicated by the health care professional in a manner that is understandable to the patient. The proposed benefits and goals of treatment must be discussed, as well as the risks and factors that might be obstacles to the success of the proposed procedure. In this communicative process, the health care professional must be assured that the patient has both an understanding and an appreciation of all of the facts that are relevant to his or her situation. Further, the patient must voluntarily accept the proposed treatment, that is, without coercion (Beauchamp and Childress 1994). The process is usually concluded when the patient is properly informed and either rejects the treatment or chooses to proceed with the procedure and signifies this by voluntarily signing an "informed consent" document or operating permit. Unfortunately, there are still some who mistakenly believe that the important matter is obtaining the signed document. It cannot be stated strongly enough that informed consent is a dynamic process that the professional must conduct with respect for the unique situation of any particular patient so that such understanding and appreciation for risks and benefits is fully apprehended. Further, since physicians occupy a position of power within the society, care must be taken that the choice is freely made by the patient.

It has been suggested that since deafness is not a life-threatening condition, a family could justifiably delay any decision on cochlear implant until their deaf child became 18 years of age and could make the decision as an adult. Although this proposal is respectful of the autonomy of both the parents, and prospectively seems to respect the autonomy of the patient, it is problematic because too much time will

be lost between diagnosis and age 18. After age 7, the brain loses much of its plasticity and precious years of hearing and learning speech have been lost for the patient, perhaps irrevocably. In the light of the ongoing support from the parents that is needed by any child undergoing cochlear implant surgery and the family's commitment to support the child through speech and hearing therapies, it is not considered propitious to seek a court mandate authorizing such surgery against the wishes of the non-consenting parents.

Consent is a particularly complex issue when a cochlear implant is considered for a child. FDA in 2000 granted approval for cochlear implants in children as young as 12 months (NIH 2010). An adult can participate in the consenting process and freely elect to have a cochlear implant, or to decline, without incurring an ethical issue. However, decision-making authority in medical care for children resides with the parents. Parents, acting as surrogate decision-makers, must consent for the surgery that allows a device to be placed inside their child's cochlea. Parents have a moral duty to act in ways that further the best interests of their children, but it is quite understandable that parents have their own values and loyalties and may find it difficult to sort out a clear picture of which process will advance the best interests of minor children who are dependent upon them to make such decisions (Beauchamp and Childress 1994). The advantages of early implantation (between 12 and 18 months) are becoming increasingly clear. "The most impressive gains were demonstrated by the children implanted between 12 and 18 months of age. Waltzman reported that over half of the children in the youngest age group achieved auditory milestones approximating those of hearing peers after only 6 months of device use. For the children implanted between 19 and 23 months, only about one-fourth attained scores within the broad normal range after 6 months of device use" (Waltzman 2006).

The young brain is most plastic, and the brain's ability to hear the sounds of speech through the implant and to recognize sounds for speech formation is optimal at an early age. Children implanted at an early age have more incidental learning of tonal changes and inflections from hearing their parents speak that augment their training. Parents have a moral duty to act in the best interests of their affected children, or at least to avoid preventable harm. Is it not a harm to deprive a child from hearing and the optimal chance for verbalized communication? Conversely, some parents argue that it is a harm to implant a device in an operation that will cause some harm to cochlear tissue, increase the risk of meningitis, and remove the child from a life within the Deaf Community, thus forcing that child to participate and compete in a hearing world.

In the ethical debate, opponents of cochlear implants have cited a variety of risks for young patients such as, uncertainty of the diagnosis, increased risk for meningitis and otitis media, as well as the inevitable damage that is done to tissues in the cochlea in the process of inserting the electrodes. The FDA reported in 2002, their awareness of 91 reports worldwide of meningitis in patients implanted with 3 approved devices, resulting in 17 deaths (FDA 2002). The Center for Disease Control and Prevention (CDC) and the FDA along with State Departments of Health began an investigation to determine risk factors that lead to meningitis in

patients under the age of 6 at the time of implant (FDA 2002). In light of the discovery that there were more cases of meningitis with the CLARION device and positioner, Advanced Bionics agreed to halt the use of its positioner and voluntarily recalled any unimplanted CLARION devices in the United States. Neither the Cochlear Limited nor MedEl Corporation electrodes uses a positioner (FDA 2002). There remains a significant population of adults and children with positioners still in place as the FDA did not recommend prophylactic removal. This is a continuing controversial issue (McCormick 2010).

The risk of contracting meningitis has always existed for implant patients, but with the advent of better immunization, the risk levels continue to fall. In the light of increased risks to patients for contracting meningitis, it is concerning that immunization rates are considerably below the optimal level in transplant patients. This raises an ethical duty for all surgeons involved in cochlear implants to be sure that all implant recipients should be immunized. Further, cases of otitis media should be treated aggressively in an effort to minimize risks from infection that might progress to meningitis (Melton and Backous 2011).

Surgeons have an ethical duty to exercise great caution in the insertion of electrodes to minimize cochlear trauma. Pediatricians caring for deaf children contemplating cochlear implant have a duty to inform, recommend, and administer PCV-13 immunization to all cochlear candidates. Since the advent of the new 13-valent immunization vaccine in 2010, replacing the 7-valent version, it is predicted that there will be a continuing drop in infections among children receiving implants. CDC guidelines recommend the 13-valent immunizations for all children from 2 months to 18 years and, 8 weeks following completion of the PCV-13 series, a single dose of PPV-23 (Melton and Backous 2011). Melton and Backous claim that cochlear implants are currently the standard of care to optimize hearing and speech for children with deafness and that the driving forces supporting this are the scientific facts about the significance of early auditory development (Melton and Backous 2011).

The FDA currently approves cochlear implants to children with deafness down to year 1 (Institutes of Health). Some suggest that the age of implantation could be lowered safely to age 6 months. However, it appears that implantation between 12 and 18 months allows more time for an accurate diagnosis, testing for additional disorders, and greater development of skull thickness prior to implantation.

Considerations favoring early usage of cochlear implants stem from results of several studies showing that although the language and hearing results from cochlear implants were variable, in most cases, it provides a clear advantage. A recent study has reported that child and adolescent evaluation of overall quality of life are about the same between normal hearing children and those with cochlear implants (Loy 2010). The overall picture has formed that the benefits from cochlear implants outweigh the burdens. Gradually, in the United States, a broad consensus has emerged around the ethical duty to maximize the learning and communicating opportunities for deaf children through the use of all means available, or total communication (TC). In the United States, children use both ASL and oral communication. Hopefully, within Deaf culture, there will also be room for both.

Cochlear implants are now being employed in most developed countries in response to childhood deafness. A growing number of studies of this phenomenon have reported on the recipient's audition, speech perception and production, and the development of spoken language. One such study carried out in an eastern Australian study in 2008 involved parents and teachers of 1,260 children who had received cochlear implants prior to age 18. Researchers concluded that the results of the study are largely positive but cautioned that parents may be slower to accept that signed communications will be part of the lives of many of these children. While making clear the benefits of cochlear implants, the study suggested that ongoing efforts must be made to meet the challenges for children with implants and their families to assist in their social development and academic achievement. The study made clear that educators who work with these children need professional development and training about the CI devices and the special needs of children with implants to help meet this challenge (Punch and Hyde 2011). Dr. Lee, a deaf scholar, claims that "*all* implanted children should have the opportunity to learn sign language at a very early age, even if only as an alternate language" (Lee 2012).

Future Issues

New prosthetic devices will inevitably enter the market. Companies that make cochlear devices are continuously at work to develop more efficient implements. For example, a totally implantable cochlear implant could be made in the future. As research develops on auditory brainstem implants, patients who might benefit will be better served as safety and efficacy issues are resolved. Currently, there is a relatively small population who qualify for ABI. "An FDA-approved auditory brainstem implant (ABI) is considered medically necessary in an individual when all of the following criteria are met: 1. Is 12 years of age or older; and 2. Diagnosed with neurofibromatosis type 2; and 3. Is completely deaf as a result of bilateral neurofibromas of the auditory nerve" (Anthem Blue Cross-Blue Shield Medical Policy 2012).

Patients with both impaired hearing and balance function, a situation especially prevalent in China and India due to ototoxic drugs and genetic mutations, may be helped in the future by an integrated vestibular-cochlear implant. The theory and technology for electrical stimulation of vestibular nerves is established, but development has been slowed by the need for miniaturization and mass production of gyroscopic sensors. It is expected that these devices will be available in the future (Lu 2011).

It is inevitable that genetics will also play a role in ethical decisions pertaining to deaf persons. Since the publication of the human genome, the cost for decoding one's individual genome has steadily declined. It is likely that more and more individuals will wish either to select for or against the expression of a particular gene in their progeny. Through genetic counseling and testing and by sharing genotypes with potential mates, couples could either increase or decrease the potential for giving birth to a child with a propensity for a particular gene.

Thus, two persons, each carriers of a recessive gene for deafness, could enhance their percentages of having a deaf child by choosing one another as biological partners with the intent of having a deaf baby.

Genetic information can also play an important role in choices made by potential parents who choose In Vitro fertilization (IVF) as a method of obtaining a pregnancy. Ethical controversy continues to swirl as to whether parents who are deaf should be able to utilize the services of reproductive biology and IVF centers to assist them in having a deaf baby. This goal could be achieved prior to implantation by aspirating one cell from each embryo created from ova and sperm of the biological couple, fertilized and incubated in the laboratory. Genetic testing can be performed on the cells collected from the embryos to determine if the embryo is positive for the trait of deafness, and only implanting affected embryos. A second method of achieving this goal would be to monitor any pregnancy of the deaf couple using prenatal genetic testing with the intent of terminating any pregnancy with a normal hearing genotype and preserving any pregnancy with a deaf genotype. Some IVF centers have refused on ethical grounds to provide such services claiming that by design, the goal is to give birth to a child with a major disability, deafness. Other centers claim they will respect the autonomy of the couple and work with them to help attain goals that are motivated by their strong sense of valuing a deaf child. Of course, a male and female who are both carriers of an autosomal-dominant gene for deafness could become pregnant through natural reproductive methods. Even as Alexander Graham Bell was unsuccessful in getting legislation to ban deaf marriages in his day, it is even more unlikely that public policies would be enacted to prevent such births in this time.

Cost is an issue that figures into the ethical considerations of cochlear implants. Now that there is evidence that cochlear implants provide the benefits of improved hearing of sounds and improved speech, common sense suggests that two would be better than one. Indeed, especially within the past decade, a number of patients with a single cochlear implant returned to the surgeon to have bilateral implants. NIH-supported scientists found that the benefits of the cochlear implant far outweigh its costs in children. “A cochlear implant costs approximately $60,000 (including the surgery, adjustments, and training). In comparison, the services, special education, and adaptation related to a child that is deaf before age 3 costs more than $1 million” (NIH 2010).

Culture is likely to remain an issue although to a lessening degree. Members of the Deaf community claim that cochlear implants undermine and jeopardize their very existence. Members of the Danish Deaf Association have claimed that “deaf children are not sick or weak children, but normal Danish children, who just happen to use another language” (Nunes 2001).

Deaf activists have argued that from the ethical principle of respect for persons, minority cultures should be preserved and respect should be shown for the minority language (ASL). Many are also concerned that if there are receding numbers of deaf individuals and a decline in deaf culture, there will be less incentive for the majority culture to provide services and assistance that allow the deaf to flourish within the larger culture – a matter of justice.

Conclusion

In this section on ethical issues, the importance of ethical principles as moral action guides in ethical decision-making has been emphasized. Respect for persons and, in particular, the autonomy or self-determination of persons with regard to their ability to freely make health care choices is highly prized in this society. Likewise, the freedom of parents to make health care decisions for their minor children is valued. However, parental decision-making for deaf children should be informed by scientific evidence concerning harms and benefits associated with the use of cochlear implants, as implied by the principles of nonmaleficence and beneficence. There is now sufficient evidence that early implantation in deaf children is clearly a benefit, assisting them in achieving both receptive and expressive communication similar to their age-related hearing peers. The principle of justice promotes a duty to treat persons and classes of persons fairly. There is lingering debate and controversy about the appropriateness of considering the Deaf community as a unique culture and whether deafness is a disability that ought to be treated. Just as the medical community is committed to providing treatment that improves vision for those with difficulty seeing, it is committed to improving the capacity to hear for persons who are deaf. The innovation of auditory prostheses in the service of deaf persons is relatively new. Researchers continue to search for inventive ways to serve this population. The new "hybrid" cochlear implant is but one example. Researchers continue to experiment with auditory brainstem implants (ABI), and more studies regarding efficacy and safety will be required in the future. Further studies are warranted, but scientific research has demonstrated both the efficacy and safety of cochlear implants when carried out by well-trained surgeons and it is predicted that bilateral transplants will become a standard of treatment in the future.

Ethical Issues in Cochlear Implantation 50

Linda Komesaroff, Paul A. Komesaroff, and Merv Hyde

Contents

Abstract

Conventional perspectives regarding the ethical issues around cochlear implantation are often simplistic and under-informed. A common assumption is that there is a choice between unequivocal acceptance of the benefit of the technology on the one hand, and a choice based on respect for the integrity and values of the Deaf community on the other. The parameters of perceived choice are explored and it is concluded that such a simplistic model fails to recognize the

complex and heterogeneous array of variables that need to be considered by, and the options that are available for, the individuals concerned, their families, and the medical practitioners advising them.

Introduction

The question of whether it is ethically appropriate to undertake cochlear implantation (see ▶ Chap. 49, "Ethical Issues in Auditory Prostheses", this volume) in young deaf babies has over a number of years been the subject of intense debate, and surprisingly little consensus has emerged. On the one side, those representing or supporting the medical community argue that deafness is a pathology, and that being able to hear is clearly *better* than being deaf, and that any therapy or technology which can help *cure* it should therefore surely be favored. On the other side, members of the Deaf community argue that being deaf is a legitimate way to be, that the meanings and values available to them, and which they share within well-functioning communities with high levels of support and solidarity, are as valid and valuable as those available to the hearing majority, and that technologies that are imposed on deaf people therefore fail to acknowledge and respect the validity and integrity of their distinct cultural resources.

Which side is right? Do the parents of a newly diagnosed deaf baby have a moral obligation to ensure that their child receives an implant at the earliest possible opportunity? Or should they rather exercise their (or their child's) cultural and linguistic right to decline the intervention and the technocratic disciplines and definition of identity that comes with it? Alternatively, should deaf children, as a matter of course, be provided with the possibility of enjoying the benefits of hearing, both in relation to their social functioning and their sensory experience? Indeed, do parents have a moral responsibility actively to support implantation (Tucker 1998)? Or is it more complex, with deaf children and their parents having more choices and alternatives than this simple dichotomy would suggest?

In public discussions about cochlear implantation, the views of hearing communities have enjoyed a natural, and obvious, advantage. The spectacular nature of the technology and the fascination with science, the public adulation of the scientist/businessmen who have promoted the technology, the access of eloquent, articulate spokespersons to the media, and humanistic discourses around curing sick children and providing expansive new opportunities for the disadvantaged, have – not surprisingly – struck a chord with both government and the public. The issue has even proved a convenient and effective device for children's hospitals – always strapped for money – to employ as part of their fund-raising campaigns.

With fewer resources at their disposal, members of the Deaf community and the organizations that represent them have done their best to challenge the cultural and linguistic assumptions underlying these positions. Their case against childhood implantation points to the validity of being a signing member of the hearing community and calls for parents to be provided with information about the Deaf community at the time of diagnosis (or discovery) of their child's deafness.

They have sought an emphasis on access to education and social services through their native sign language rather than on medical interventions that are directed toward enhancing their functioning within dominant (hearing/speaking) cultures. Attempts to move the argument beyond technical, medical, and audiological issues highlight the importance of deaf culture and the central place of a native sign language in deaf people's lives (see Lane and Bahan 1998; Ladd 2007). A recent resolution of the World Federation of the Deaf (2011) reaffirmed the need for information on sign language development to be provided to parents of children with cochlear implants, drawing on a claim to their "rights" as members of a cultural and linguistic minority. This perspective is supported by several conventions of the United Nations (see Komesaroff 2000), in particular the UN Convention on the Rights of People with a Disability (United Nations 2006; see Hyde 2007), which asserts the rights of sign language users to access and participate in the full range of life experiences. Article 24, section 3(c) of the convention calls for the education of children who are deaf to be "delivered in the most appropriate languages and modes and means of communication for the individual, and in environments which maximize academic and social development."

There can be no doubt that the pathologization of deafness has reinforced the assumption (unsupported by research; see Hyde 2005) that participation in a signing culture will undermine the ability of deaf children to acquire and use speech and, as a result, to function and thrive in (hearing) society. As such, a common myth is that children with implants need to be educated in a non-signing environment to avoid interference from sign language on spoken language development that has resulted in an "endangerment" of sign languages (see Murray n.d.). Cochlear implantation is the dominant approach to treating congenital deafness among people in most Western countries (Komesaroff 2007b) and while the counter-arguments of the Deaf community that deafness should be regarded as an example of cultural difference rather than as a medical pathology have drawn attention to the existence of a contrary perspective, these appear to have done little to disturb or disrupt the status quo and majority cultural assumptions have prevailed.

As a result, the dilemmas faced by parents and medical practitioners remain as stark as ever. The problem is posed as one requiring a clear decision between two fundamentally opposed cultural and ethical positions. This has led to considerable uncertainty and anxiety among all concerned, but especially among the parents of newly diagnosed deaf babies or children. How should they respond to this dilemma of pathology or culture, on which the future welfare and happiness of their children would seem to depend? How should they manage such ambiguity? How do they – and we – answer when asked "What should we do?."

As with other apparently intractable ethical dilemmas, in this one, there is a need to consider the assumptions lying behind the issues and to explore the possibilities for dialogue between the two opposing positions. We need to reflect on the frameworks of knowledge and culture that have generated the two viewpoints and open up the possibility of a third way that incorporates respect for both. We need to be able to accept that implantation, not unlike other areas of medical intervention, can be problematic, but that so also is the unconditional rejection of implantation

(see ▶ Chap. 48, "Ethical Implications of Sensory Prostheses", this volume). In the process, we are compelled to disrupt both the conventional medical view of deafness as pathology (with its associated social controls implicit in surgical intervention) and the cultural view of deaf people as members of an autochthonous, independently functioning, linguistic, and cultural minority. Dialogue between the two discourses will require recognition of the possibility of complex, multifaceted identities that enable individuals to inhabit multiple social groups simultaneously and to operate competently in diverse cultural domains.

In reality, neither the Hearing nor the Deaf World is unitary or homogenous. Cochlear implantation exists within diverse, complex, and changing social environments in which new meanings are constantly being negotiated and contested. The processes by which such meanings arise and pass away, furthermore – as in all negotiations around ethical values – are highly dependent on local conditions, including individual needs, personal preferences, and cultural biases. These can be unpredictable and subject to change, along with the specific circumstances that apply to particular cases. If we are to develop an ethical discourse around cochlear implantation, therefore, that is capable of encompassing the full complexity both of the issues and of the decision-making processes associated with them, we need to go beyond the conventional formulations and the mere acknowledgment of linguistic and cultural rights. Instead, we will be obliged to question prevailing assumptions about deafness, on all sides, and to find ways to actively promote the deep cultural and ethical dialogues by which difference is realized and individuality developed and expressed.

What is the nature of a deaf life? How can and do deaf people contribute to the lives of all people? Can cochlear implants be viewed as one of a multitude of devices or tools to be used at the discretion of deaf people, depending on their purposes, social contexts, and value frameworks? Deconstruction of existing value systems allows us to expand the possibilities for ethical action (Komesaroff 2008). This does not lead to definitive, outcome-focused resolutions of ethical dilemmas but to the reactivation of a process within which productive communication and dialogue across difference can occur. Such an approach emphasizes the multiple aspects of implantation itself along with the multiple readings of deafness, together with the sequence of decisions that must be made by parents and deaf people (as against a unitary "decision"). Opposite and contradictory points of view necessarily abound – and they need to coexist. Examination of the lived experience of deaf people's lives allows reductionist views of "deafness versus hearing" to be challenged and new directions for the medical practice of implantation to be opened up.

Historical Perspective

Aside from the "normal" risks and insured liabilities associated with the conduct of any surgery, the introduction of ethical considerations into cochlear implantation was initially seen as unnecessary or even intrusive

(Power and Hyde 1992; Hyde 1995). Medical clinicians, parents of young deaf children, and even some deaf individuals themselves, all saw the debates about ethics as imposing an unwanted limitation on their right to choose. After all, the process and its possible outcomes seemed obviously to be "good" (Hyde and Power 2000).

At least in this regard, 20 years later, a lot has changed. Against this initially hostile context, considerable progress has been made by all the key stakeholders. The claims of "genocide" (see Lane 2005; Ladd 2007), asserted in the heat of the divisive and emotive rhetoric by some groups against surgeons and implant programs, have been shown to be extravagant and unfounded. At the same time, the depiction of implantation as the "cure to deafness," so commonly portrayed in the media (Komesaroff 2007), has also proven to be incorrect and exaggerated. An elaborated understanding of both "risk" and "benefit" has been incorporated into the protocols used before surgery and into the consent procedures routinely observed with parents and deaf people (Punch and Hyde 2011a, b). The extent of the risk-benefit analysis has been significantly broadened to include recognition of the social, cultural, and educational dimensions along with the anatomical and surgical factors.

Nonetheless, there remains much to be done. Wider issues such as identity, well-being, and social inclusion and isolation need further exploration. The implications of research that demonstrates adverse educational and social consequences of a child's deafness, regardless of implantation, need to be considered. The recognition that deaf children with implants may achieve educational outcomes at the level of those associated with "hard of hearing" students (Hyde and Punch 2010) suggests that the analysis of risk and benefit needs to be extended still further, across a broader time frame, to allow the assessment of educational, social, and vocational outcomes into young adulthood (18–24 years of age).

An accurate understanding of the available facts is important. It has been argued by Deaf communities that the decision about whether or not to undergo a cochlear implant can be left until the individual concerned is an adult. In addition, medical professionals have advised parents that the learning of sign language can be delayed until later in life, according to preference. However, there are time constraints to both decisions. It is now generally accepted that surgery and rehabilitation must occur as early as possible in a deaf child's life if the best outcomes in the acquisition of a spoken language are to be attained. Similarly, there is a critical period within which a first language needs to be acquired (whether it is a spoken or signed language) for native-like fluency to be possible.

Rather than retaining an exclusive focus on whether or not to implant a young child, there is a growing recognition of the need for ongoing *re*-evaluation of the *multiple* decisions to be made throughout a deaf person's life. The initial decision about whether or not to implant is made by parents based on the information available to them at the time. As their deaf child grows and shows preferences for various means of communication, thrives or struggles with education, and identifies with some individuals or groups over others, he or

she may make unexpected and changing decisions about the use of their implant and how it relates to their developing identity and well-being (see ▶ Chap. 22, "Neuroethics and Identity", this volume).

In this context, it may be better and more appropriate to move away from the understanding of cochlear implants as a cure for deafness, and to regard them instead as an example of one of multiple technologies that can be used by deaf people to navigate their way through life. We now recognize that deaf people make use of implants in different ways at different times and in different contexts. Alongside their use of an implant, they may use sign language, interpreters, computers, telecommunication devices, and so on – depending on what is needed and what works best at the time, and in relation to particular social, recreational, and vocational needs. The ability to move seamlessly between different means of communication is an important indicator of both the acquisition of effective competence as a communicator and of mature and robust personal identity.

The Theory of Minimal Adaptation, proposed by Bernard Farber and retained in use by more recent researchers (Farber 1960; Brown et al. 2008), may provide a useful framework for explaining the ways in which people from differing perspectives can respond to challenges in constructive and nonthreatening ways. According to this theory, individuals typically try to solve issues in incremental steps, beginning with changes that differ in the least possible way from their current positions. For example, to hearing parents, providing their child with a cochlear implant may initially offer the least adaptation necessary to preserve *their* cultural and linguistic heritage and aspirations for the child. As time goes by, and further changes typically become necessary, however, they may find it possible to shift more definitively from their initial position or decision to embrace sign language and deaf culture, ultimately moving further toward what is considered a more "Deaf World" view.

If this is how decision-making occurs in practice – and indeed, is encouraged – the time frames in which the risk-benefit analysis around cochlear implantation is conceived and the consent processes are negotiated need to be extended. As deaf infants with cochlear implants grow and develop, their identities will unfold in relation to the range of experiences to which they are exposed and the opportunities they encounter. The development of a mature identity cannot be understood simplistically in terms of a choice between the identity of a "hearing person" and that of a "deaf person." Even expanded descriptions, (e.g., Bat-Chava 2000), are inadequate and inauthentic and thus unable to reflect the more multilayered and complex outcomes that are likely.

There are many other factors that also need to be taken into consideration. For example, recent studies (Punch and Hyde 2011a, b) have identified a range of challenges that arise across the years of primary schooling, through adolescence and into emerging adulthood for deaf people with implants. This research suggests that issues of social isolation, some areas of school achievement (e.g., literacy and numeracy), and reduced social and emotional well-being may also need to be included in the discourses about ethics and shared meaning around implantation.

Emerging Adulthood, Resilience, and Well-Being

Of itself, hearing loss does not inevitably pose a risk to successful transition as an emerging adult. However, significant hearing loss sustained in childhood or adolescence creates a vulnerability that can limit the capacity of individuals to adapt to the demands and opportunities presented in emerging adulthood and threaten psychological well-being and achievements. Factors contributing to this vulnerability can include communication difficulties with family members and peers, a limited range of social relationships, feelings of isolation, reduced school achievement, lowered expectations by others, and feelings of dependency (Valentine and Skelton 2007). These may limit the development of "resilience" and contribute to stress, anxiety, and lowered measures of well-being and life satisfaction (Gascon-Ramos 2008). Deaf and hard of hearing (DHH) individuals within a hearing environment are invariably faced with daily obstacles and challenges relating to communication difficulties and a range of social and structural barriers, including stigma and prejudice, contributing to personal and social problems in emerging adulthood (Lukomski 2011; Meyer and Kashubeck-West 2011; Punch et al. 2004).

The mechanisms underlying the development of resilience are not entirely clear. Meyer and Kashubeck-West (2011) concluded that interactions between environmental and individual factors are of particular concern for the development of resilience in young adults who are deaf. However, others such as Valentine and Skelton (2007) and Gascon-Ramos (2008) view resilience and well-being as a consequence or outcome of the identity that a DHH child develops; in this view, the use of a sign language and exposure to a deaf culture is seen as being causally related to a stronger sense of identity and subsequently greater resilience and psychological well-being through emerging adulthood. In contrast, Hyde and Power (2006) argued that resilience can also be typified as the capacity to "overcome deafness" and to succeed, "despite" the presence of hearing loss. The assumption – they claimed – is often that resilience is associated with success in terms of the individual developing proficiency in the use of a spoken language and in circumstances where normally hearing adults are seen to succeed. Although this last vision of resilience is naturally appealing to many parents, it does not account for the diversity among people with hearing loss and the differing environments in which they develop and learn; furthermore, it can also be a strong stigmatizing influence for those who cannot reach anticipated standards and it can create lowered perceptions of self-efficacy and worth (Hyde and Power 2006; Punch and Hyde 2005).

Another area in which data are lacking is that of DHH emerging adults and their psychological well-being. Meyer and Kashubeck-West (2011) reviewed the small amount of research on emerging adults who are deaf and found that it focused on pathological indicators such as might be observed in psychological distress or during periods of unemployment. They found that very little emphasis has been placed on potentially positive psychological constructs such as the development of well-being and life satisfaction.

Emerging Adulthood and Identity

In many countries, the great majority of DHH children grow up in homes and go to schools with normally hearing members, without exposure to a sign language and with the expectation by both parents and teachers that a "hearing" identity is the objective or desirable outcome (Hyde and Power 2003; Punch and Hyde 2011a). The almost universal use of cochlear implants in significantly deaf infants and young children has further entrenched this expectation (Hyde et al. 2010; Punch and Hyde 2010). Such an implicit and unquestioned assumption of a key ethical goal, however, often sets the scene for a clash with the demand for greater personal autonomy associated with adolescence, which for young DHH people involves attempts to adapt to the transitions and challenges associated with emerging adulthood within expanding social, vocational, and educational networks, including engagement with other young people facing similar issues.

In this context, some studies suggest that the use of a sign language and identification with a Deaf community can be associated with higher levels of self-esteem and psychological well-being (Valentine and Skelton 2007). Other researchers have found four specific deaf identities (Fischer and McWhirter 2001; Glickman and Carey 1993): "hearing," "marginal," "immersion," and "bicultural" – to describe individuals' "orientation[s] to an affiliation with the Deaf Community and Deaf Culture" (Fischer et al. 2001, p. 358). In a similar vein, Bat-Chava (2000) described three identities: "culturally deaf," "culturally hearing," and "bicultural."

While these categorical models may offer some useful – albeit perhaps oversimplified – descriptions of the identities that young deaf people may develop, they do not take account of the complexity of the experiences of emerging deaf adults in contemporary societies. For example, a recent study (Hyde and Punch 2011) found that some hearing parents of children with cochlear implants valued the use of signing as a way for their children to establish a connection to other deaf people and, perhaps, a sense of belonging to the Deaf community, and that in adolescence, some of the young people with cochlear implants themselves for the first time developed an interest in the Deaf community.

Any simple description of the nature of the identity formation of emerging deaf adults would seem insufficient to describe the complex interplay of variables and opportunities experienced by young deaf people in contemporary post-school transitions. It is possible that other theories of identity may prove more applicable, such as that proposed by Cass (1996) to describe the isolation, confusion, and stigma often experienced by individuals with alternative sexual orientations, or the intersectionality theory of Crenshaw (1991), which suggests that various biological, social, and cultural categories do not act alone and may interact in different environments to form more complex accommodations of identity.

Cochlear Implantation, Transition, and Well-Being

As we have seen, there are strong expectations among many parents, implant providers, intervention and educational service providers, and some deaf people themselves that the use of cochlear implants will "conquer deafness" (Wheeler et al. 2009). Research findings have shown significant benefits on many measures, but not as yet universal outcomes from the perspectives of parents, teachers, or young deaf people themselves (see Punch and Hyde 2011b for a review). A recent Australian study has found that social participation and emotional well-being remain consistently problematic as children with cochlear implants reach adolescence. It appears that even cochlear implant users with excellent spoken language development experience the phenomenon of "social deafness," a term describing the effects of hearing loss in social interactions involving groups of people or in noisy environments, such as in post-school education, work and social environments (Punch and Hyde 2011a). Although potential school-to-work transition, career development, and psychological well-being outcomes may differ among DHH young people with and without implants, many issues, challenges, and barriers are likely to be common to both groups.

In particular, DHH young adults are at greater risk of attrition from further education and training, of unemployment and underemployment, and of lower levels of psychological well-being and life satisfaction. Further, there has been limited study of the period of emerging adulthood as experienced by DHH people who have been sustained users of cochlear implants. To realize the benefit of major, ongoing public investment in health and education systems, ameliorate the effects of growing up with hearing loss and achieve economic parity, further data are needed in these areas before a more complete risk-benefit analysis can be undertaken and incorporated into consent processes.

Conclusion

We have argued that conventional formulations regarding the ethical issues around cochlear implantation are excessively simplistic. The assumption that in every case, a simple and unequivocal choice has to be made between unconditional acceptance of the technology and the hegemony of the hearing culture, on the one hand, and respect for the integrity and values of the Deaf community, on the other, fails to recognize the complex and heterogeneous array of variables that need to be considered by, and the choices that are available for, the individuals concerned, their families, and the medical practitioners advising them. The familiar discussions focusing on abstract, context-independent categories such as autonomy, informed consent, and beneficence, furthermore, systematically obscure the uncertainties of knowledge and science, the variety of value positions, the ambivalence commonly experienced by parents and carers, and the varying psychological and cultural needs of deaf and hard of hearing children and their families.

The process of dialogue around ethical issues is complex, and involves many factors, such as individual circumstances, value preferences, and social and cultural settings, which often evolve and change over time. Unsurprisingly, it is rarely the case that there is a single point of view that is clearly preferable to all others; rather, each typically contains elements of truth as well as tensions and uncertainties that need to be resolved in relation to the prevailing circumstances and the available resources. Through this dense plenum of values that characterizes the ethical territory of hearing and deafness, individuals and families negotiate their trajectories. In most cases, they do not find themselves compelled to make an irrevocable commitment to a single, preformed identity: between, for example, that of a person who accepts without question the benefits of technology or that of membership of a signing community. On the contrary, for the most part, identities are composed and re-composed according to circumstances, experiences, and changing conditions; they may be fluid and multifaceted; and they may remain subject to uncertainty, ambivalence, and critical questioning.

Typically, decisions are made locally, in relation to immediate circumstances and challenges, rather than in reference to large-scale principles or long-term anticipated outcomes. Accordingly, the ethical reflections that support these decisions are not purely theoretical. They depend sensitively on local conditions and personal preferences, as well as on knowledge and the cultural valorization of alternative courses of action. Detailed knowledge of the findings of empirical research into the various factors influencing the welfare of young people and developing adults is essential for an adequate understanding both of the issues themselves and of effective responses to them, including research into the conditions for the emergence of resilience and psychosocial well-being, and problems and challenges in relation to education. In other words, ethical discourse involves a relentless process of exposing questions, of clarifying the empirical conditions that shape the possible outcomes, and the subsequent mapping of the ethical and social meanings thereby generated.

The time has come to move on from the rigid polarization between implantation and Deaf cultural characteristics such as the use of sign languages to more open, tolerant flexible arrangements that incorporate hybrid combinations of the various possibilities within a cultural field that supports and stimulates ongoing critical reflection and review.

Sensory Enhancement

51

Karim Jebari

Contents

Abstract

Sensory enhancement is a form of human enhancement that aims to extend the sensory capabilities of a person beyond what is possible for a normal human. Sensory enhancement can consist in either an enhancement that improves a sense or that extends that sense to perceive light, sound, tactile stimuli, or chemical traces that are beyond the human range. A sensory enhancement may also add a new sense, such as electroreception or modulate a sense so that it can perform completely new functions, such as echolocation (biosonar). This chapter argues that sensory enhancement could be implemented in mainly two ways: either via the application of digital technology or by genetic engineering of the human body. The potential of augmented reality (AR) and of brain-computer Interface (BCI) technology is also explored in the section on digital

enhancement. The section on genetic engineering will mainly be concerned with the potential of horizontal gene transfer (HGT). Three arguments on the normative aspects of sensory enhancement are also presented in this chapter. The first considers the instrumental value of being able to perceive new forms of artistic expression. The second concerns the idea of diversity and whether sensory enhancement could increase human diversity. The third argument departs from the "capabilities approach," formulated by Amartya Sen and Martha Nussbaum, and sketches out the position that we may be deprived in comparison to some possible future enhanced people, even if we do not regret being so.

Introduction

Sensory enhancement is in this context an instance of *human enhancement*. Thus, a correction of deficient hearing or sight is not covered here. At the moment, glasses and cochlea implants are not sensory enhancement technologies. Should telescopes and microscopes be defined as sensory enhancement technologies? Here the distinction is more tenuous and based on what we perceive to be part of a person's abilities. For something to count as an enhancement, this must add or extend a person's functioning, or ability to do something. Clearly we do not believe that a person who owns a telescope has the ability to see the Galilean moons, even if that person is in some more general sense able to do it. Human enhancement technologies ought to therefore be seen as artifacts that are to a certain degree integrated with our persona. According to a narrow view, only things that are physically integrated, i.e., attached or assimilated to the body, ought to count. A clear example of this would be a vaccine. On a more inclusive view, devices that form part of a person's mental self-representation should also be included. On this view, if a person perceives glasses, clothes, contact lenses, and (perhaps) a smartphone to be part of his or her body, these devices count as human enhancements. This vague characterization will vary in different contexts and across generations, but it will suffice for the purposes of this discussion. Another distinction that ought to be considered is between a sensory enhancement that allows us to perceive a sensory input without giving us a new sensory quality and an enhancement that would literally change how we see the world. For example, a thermographic camera forms an image of infrared light using visible light. An observer can therefore indirectly see infrared light. This sensory experience probably differs from what it might be like to be able to perceive infrared directly, which of course may differ radically between different individuals and species. However, an indirect experience of the world may be just as useful for practical purposes as a direct one. We should therefore include technologies that allow people to "see" indirectly in our definition of sensory enhancement. Another relevant distinction is between enhancement of our *sensory capacities* and the enhancement of our *perception*. Whereas the first changes *what* we perceive, the second changes *how* we perceive. As an example of perceptual enhancement,

consider some drugs that allegedly enhance the way we perceive music, and allow us to distinguish between subtle nuances. The difference here is that whereas sensory enhancement is primarily informational, perceptual enhancement is primarily phenomenological. This chapter will not be concerned with perceptual enhancement.

Some of the proposals that have been made for human enhancement refer to new and improved sensory functions. For example, concrete research is currently being performed on a bionic contact lens the display of which will be superimposed on what one sees naturally. Other proposals include improved vision (ultraviolet and/or infrared wavelengths), more acute hearing, and chemical sensors. Although such possibilities have been mentioned in the literature on enhancement, sensory enhancement is not the main topic of a single publication that is tracked in the philosophical database *phil papers* or the medical database *pub med*. This chapter will argue that this lack of attention is regrettable, due to the potential importance of sensory enhancement. It will isolate the issue of sensory enhancement from the more general issue of enhancement, covering both the more speculative and the more realistic possibilities for enhancement, but with a clear emphasis on the latter.

Outline of the Opportunity Space

Any plausible account of future developments demarcates the possible and interesting from the purely fantastical. This is no trivial task. Yet, any discussion of this nature requires that we anchor our expectations along some space of possible outcomes. I suggest a possible heuristic for doing this in the context of sensory enhancement. Although physics sets a definitive boundary from what we can expect to be possible, the boundary set by biology is narrower and more interesting. More specifically, I propose that when thinking about the possibility space of potential sensory enhancements, we confine ourselves by the boundary set by animals in the phylum *chordate* (vertebrates). While the species diversity within this phylum is formidable, ranging from fish and bird to mammals, these animals share a relatively well-developed brain, complex sensory organs, and a circulatory system with a heart (Romer and Parsons 1986). According to the proposed "chordate-heuristic," a biological function in the realm of sensory perception that is possible in this phylum might be possible for humans in the future, given the appropriate technology.

In this chapter, two technology trends are extrapolated to provide a plausible basis for these considerations: the rapidly advancing prowess of genetic engineering, in particular horizontal gene transfer, or HGT. This technology consists in the transfer of genes between organisms. The second technology trend is the miniaturization and price reduction of processing power and the probable future ubiquity of computers and sensors. Two technologies are of particular interest here. First, augmented reality, or AR, is computer-generated sensory input that is superimposed on reality. This makes mediation of sensory inputs possible.

The second technology is brain-computer interface, or BCI, which refers to a device that allows direct communication between the central nervous system and a computer by means of electrodes. Such devices are already used in cochlea implants and artificial retinas.

Digital Senses: From Augmented Reality to Brain-Computer Interface

Augmented Reality

As computers and digital sensors have become smaller, cheaper, and more powerful, their usefulness for enhancement purposes has become evident. It is reasonable to conjecture that any sensory data gathered by a machine that is either wearable or possible to connect to the internet could, with the appropriate interface, add to our own sensory experience. Increased digitalization has made sensory-enhancing technology cheaper and better. Night goggles are, for example, widely used by military forces and police officers all over the world. As these goggles and other similar technology increasingly rely on computers, we can reasonably expect that night vision might become cheaper and more suited for nonprofessional use. Digital hearing aids can enhance audition both by amplifying sounds and enhance signal to noise ratios in the environment. However, much more radical enhancement can be achieved by "outsourcing" our perceptual apparatus with the help of emerging technology. Consider the field of augmented reality or AR. Augmented reality is a live, direct or indirect, view of a physical, real-world environment whose elements are augmented by computer-generated sensory input such as sound, video, graphics, or GPS data. A head-mounted display (HMD) places images of both the physical world and registered virtual graphical objects over the user's view of the world. Project Glass is a research and development program by Google to develop an augmented reality head-mounted display (HMD). This product will, according to Google, be available in the consumer market in 2014 (Goldman 2012).

Bionic contact lenses are being developed to provide a virtual display that could have a variety of uses from assisting the visually impaired, to the video game industry. These devices will have the form of conventional contact lenses with added bionics technology. These lenses will eventually have functional electronic circuits and infrared lights to create a virtual display (Collier 2010). Leading researchers in this field state that "Looking through a completed lens, you would see what the display is generating superimposed on the world outside" (Hickey 2008). In 2011, Lingley et al. created and tested in vivo a functioning wirelessly powered prototype with a single-pixel display. These contact lenses were tested on rabbits and showed no adverse effects (Lingley et al. 2011).

The potential to enhance vision and hearing with the help of AR is quite significant. A likely development in the near future is what is sometimes referred to as "the internet of things" (Ashton 2009). The idea behind this concept is that

ordinary things will increasingly be equipped with identification tags, computers, and sensors that feed their information through the web. Thermal imaging cameras are already widely used as tools for surveillance, and are becoming so cheap that they are available as consumer products. Increasingly, these cameras are equipped with connectivity, allowing users to tap into them via Smartphone apps. Night vision cameras and other electronic equipment with sensors capable of obtaining sensory input beyond the human ability could easily be mounted on cars, streetlamps, and signposts and thus provide wireless information to AR systems, thereby providing users with night vision, vision in the UV-range, telescopic vision, and other kinds of enhancements. The ability to accurately measure distance, size, and determine the mass, density, and the trajectory of an object are typical examples of enhancements that are well suited to an AR system. Hearing could just as plausibly be outsourced to sensors embedded in the environment. Sensors could pick up ultra- and infrasound, enhance accuracy, and add information about the source of the sound.

Electric noses are devices that can effectively detect small concentration of chemicals in confined spaces. With direct applications in security, medicine, food production, and chemical safety, this technology has a clear commercial potential. With an appropriate interface, such as either AR or a brain-computer interface, this technology could be used to enhance our sense of smell. Like connecting an artificial limb with the somatosensory system, or directly stimulating ocular nerves to repair sight, olfactory enhancement has the potential to profoundly affect functioning. Whether or not these electric noses will enter the consumer market for enhancement purposes remains to be seen (Wilson and Baietto 2009).

Magnetoreception is a sense which allows an animal to detect a magnetic field to perceive direction, altitude, or location. It has been hypothesized that the ability to sense the Earth's magnetic field is essential to some birds' ability to navigate during migration (Walcott 1996). Magnetoreception in humans has been achieved by magnetic implants used as non-permanently attached artificial sensory "organs" (Nagel et al. 2005). Small neodymium magnets can be placed under the skin (usually the fingertips) so that the movement of the implant in the presence of magnetic fields can be felt by the individual. These implants can in this way be used to convert nonhuman sensory information into touch (Hameed et al. 2010). As with AR, this kind of enhancement does not provide the user with a new sense directly. Rather it allows a user to gather new information but via the user's sense of touch. These implants are to some extent used by subcultures that experiment with body modification (Norton 2006).

Brain-Computer Interface and Sensory Enhancement

Since AR superimposes sensory data in way that we can interpret, it only gives us a "superficial" enhancement. For example, a device that can allow a user to "see" UV light will represent this light through the user's AR device into light that the user is able to perceive. Although this might be interesting and useful, it does not

fundamentally alter our perceptual apparatus. However, brain-computer interface (BCI) based devices could do just that. A BCI connects the central nervous system directly to a computer, and allows information to be transferred between these two systems through electrical impulses. Cochlear implants are prosthetic devices that use this technology and that feed sensory information directly to the auditory nerve. BCI implants could in theory mediate sensory input without adapting it to the range of the human ear or eye. Thus, a BCI-mediated sensory experience would probably differ from that mediated via AR. Whereas we are likely to see AR enhancements of the kind discussed above in a few years, BCI enhancements require several scientific breakthroughs regarding both miniaturization and the understanding of the relevant mechanisms in the brain. In addition, since a BCI that provides this amount of information to specific parts of the brain requires an invasive procedure, we are not likely to see this kind of enhancement to be widely adopted unless a noninvasive (transcranial) method to accurately target parts in the brain associated with perception is devised. Although a novel interest for noninvasive electrical stimulation has had a kind of renaissance, neither of the two main technologies, i.e., transcranial direct-current stimulation and transcranial magnetic stimulation, have yet been used to produce sensory experiences similar to those of a cochlea implant.

Gene Transfer

Horizontal gene transfer (HGT) consists of the transfer of genetic material between organisms. Since genes are in sense instructions to produce proteins, new genes imply new proteins and thus new abilities. For example, this is the technique behind GloFish, a zebra fish with genes that encodes the green florescent protein, originally extracted from jellyfish (Zhiyuan et al. 2010). HGT experiments in animals have so far failed to produce results that would justify performing gene transfer in humans; however, gene transfer techniques may eventually be used for enhancement purposes. While any existing animal sensory modality suggests a possibility for future enhancement, visual enhancements are of particular interest (Jacobs et al. 2007). An inherent plasticity in the mammalian visual system may permit the emergence of a new dimension of sensory experience based solely on gene-driven changes in receptor organization. However, it should be noted that sensory systems are in large part integrated in the central nervous system. We should not expect to get a bird's vision by simply implanting genes that alter the form of the eyes. To benefit from bird's visual systems, we also need some of the neurological hardware that birds have and that we lack. This kind of gene transfer is therefore much more complicated and advanced than that which allows the zebra fish to glow. Keeping that in mind, I will now explore some possible sensory modalities that could be of interest for researchers to consider.

Although human vision is quite good when compared with that of other mammals, the visual systems that some birds enjoy are simply formidable. There are two sorts of light receptors in the bird's eye, rods and cones. Rods, which contain the

visual pigment rhodopsin, are better for night vision, because they are sensitive to small quantities of light. Cones detect specific colors (or wavelengths) of light, so they are more important to color-orientated animals such as birds. Most birds are tetrachromatic, i.e., in possession of four types of cone cells, each with a distinctive maximal absorption peak. In some birds, the maximal absorption peak of the cone cell responsible for the shortest wavelength extends to the ultraviolet (UV) range, making them UV-sensitive. Birds can also resolve rapid movements better than humans, for whom flickering at a rate greater than 50 Hz appears as continuous movement. This means that while humans cannot distinguish individual flashes of a fluorescent light bulb oscillating at 60 Hz, birds like budgerigars and chickens have flicker thresholds of more than 100 Hz. Birds can also detect slow moving objects. The movement of the sun and the constellations across the sky is imperceptible to humans, but detected by birds. The ability to detect these movements allows some migrating birds to properly orientate themselves (Jones et al. 2007).

Many animals have better night vision than humans, the result of one or more differences in the morphology and anatomy of their eyes. These include having a larger eyeball, a larger lens, a larger optical aperture (the pupils may expand to the physical limit of the eyelids), and more rods than cones (or rods exclusively) in the retina. Among other animals, cats and dogs have a layer of tissue in the eye that reflects visible light back through the retina. This tissue, referred to as “tapetum lucidum,” increases the light available to the photoreceptors, allowing the animal to see in poor light conditions.

Some animals have been known to perceive infrasonic waves going through the earth caused by natural disasters and can use these as an early warning. Infrasound is also used for long-distance communication by many of the large mammals. For example, elephants produce infrasound waves that travel through solid ground and are sensed by other herds using their feet, although they may be separated by hundreds of kilometers (Payne et al. 1986). These calls range from 15 to 35 Hz and can be as loud as 117 dB (Langbauer et al. 1991). Other animals are able to perceive ultrasound. For example, bats can detect frequencies beyond 100 kHz, possibly up to 200 kHz (Popper and Fay 1995).

Echolocation is a biological sonar used by bats, dolphins, and other animals. They use echolocation by emitting sounds out to the environment and listening to the echoes that return from the various objects. The animal can measure the range to the objects surrounding it by measuring the time delay between the animal’s call and the echo. The relative intensity of the sound and the difference in time delay between the animal’s ears gives the animal an idea of the horizontal angle of the object. Echolocation requires, in addition to the ability to emit sounds at high frequencies, also the ability to construct a detailed representation of a complex environment from sound. Thus, although echolocation does not require new sensory modalities, it requires neuronal structures alien to the human brain (Jones 2005).

Electroreception is the ability in some animals to sense electrical stimuli. It has been only been observed in aquatic or amphibious animals, since water is a much

better conductor than air. Electroreception is used in electrolocation (detecting objects) and for electrocommunication. Passive electroreception relies upon ampullary receptors which are sensitive to low (below 50 Hz) frequency stimuli (Collin and Whitehead 2004).

While these sensory modalities might prove very difficult to transfer to a human organism, the mere fact that they are possible in species that are relatively similar to us suggests that it is possible. We should also distinguish these *biologically* possible sensory modalities with other, merely *physical* possibilities. While it might be consistent with the laws of physics to be able to perceive neutrinos, this is not likely to happen for any organism that is even remotely human. In comparison, the biological changes for some of these sensory modalities are quite modest.

Should We Accept Sensory Enhancement?

Although human enhancement has been part of the bioethics debate for more than a decade, the issue of sensory enhancement has garnered little attention. A possible explanation may be that sensory enhancement seems to yield small benefits in contrast with, for example, cognitive enhancement. The claim that the benefits of sensory enhancement will at best be modest seems plausible. However, some justification for this kind of human enhancement is still possible to formulate. In this final section, this chapter will sketch out three arguments in favor of sensory enhancement, all of which need to be explored further.

Instrumental Value: To Perceive New Value Structures

The English expression "Art for art's sake" expresses the idea that art has intrinsic value, separate from whatever utility it may provide. This view is often defended by philosophers who ascribe to pluralist notions of intrinsic value, such as William Frankena and others (Frankena 1973). Some forms of artistic expression such as music, photography, and cuisine are directed to one or more specific sensory modalities such that these senses are necessary to experience the aesthetic beauty or excellence conveyed by these expressions. Sensory modalities are thus instrumental for us to be able to perceive or experience these sources of value. If some sensory enhancements became widespread, art that would require these enhancements to be perceived might be produced. Ultrasound musical instrument is one possible example. Although some sensory modalities are of little practical benefit, such as the ability to perceive UV light, these enhancements may be instrumental for us to experience and express new forms of human creativity. Although the deaf community can plausibly make the case that being unable to hear does not imply that one's life contains less welfare than otherwise, they cannot deny that being deaf deprives the person from experiencing a certain form of human expression that is, if not intrinsically valuable, at least very enjoyable (Cooper 2007). Music as such is

not the only possible form of expression, and we may all be “deaf” with respect to the as of yet unexplored and unimagined forms of cultural activity that may involve nonhuman sensory modalities. The argument against deafness can thus be deployed in favor of extending the range of human sensory modalities. It is worth noting that this argument is not specific to sensory enhancement. For example, some forms of cognitive enhancement may allow us to appreciate some literary works or the aesthetic qualities in abstract mathematics.

However, it is not obvious that the analogy between music and a hitherto unknown but possible source of intrinsic value can be made. Whether this analogy is adequate depends on the source of value of music and other existing art forms. Does the value of art rest on the communitarian importance of participating and sharing an experience across time and cultures? Or does the value of art depend on its intrinsic aesthetic qualities? An art form based on nonhuman sensory modalities would not in the same sense carry these communitarian values. However, some art theoreticians argue that art has cognitive value, in virtue of its capacity to increase our understanding on some topic (Schellekens 2007). Furthermore, these hypothetical nonhuman art forms may be just as beautiful and aesthetically pleasing as existing art forms. A similar argument in favor of expanding sensory modality has been formulated by Nick Bostrom. He argues that although our human limitations are so pervasive that we fail to notice them, there is likely to be a huge range of modes of being in and perceiving the world that allow us to engage in very valuable activities. It is therefore important to explore these possible modes of being (Bostrom 2003).

Two Arguments from Diversity

The human species is extraordinarily homogenous in comparison with other primate species, which often include a number of subspecies. It has been hypothesized that this relative homogeneity may be due to a great disaster in our recent evolutionary history (Ambrose 1998). This homogeneity may prove problematic. Diverse societies are more innovative and more adept to understand disruptive social or natural dynamics (Kandler and Laland 2009). Homogenization may expose us to risks if our limited frames of reference reduce our ability to understand and imagine possibilities and risks. Remember that for many unexpected catastrophic events, it is our failure to anticipate these events that make them so dangerous (Taleb 2007). By increasing diversity among the constituent members of our global civilization, we may increase the possibility to imagine and anticipate some of the risks that we have as of yet failed to conceive of. Sadly, the modern condition seems to reduce the diversity of opinions, values, and beliefs. Urbanization, globalization, and a truly global commercial culture have already led to the elimination of many languages and cultures (Abrams and Strogatz 2003). As mankind will become predominantly a species of city dwellers in the twenty-first century, this process will probably accelerate. As sensory modalities constitute

literally a new perspective on the world, the proliferation of different combinations of perceptual apparatuses may contribute to a significant degree to different ways of relating to and interfacing with the world. As has been discussed in this chapter, many of the sensory modalities that may become possible include trade-offs. There is no "perfect sense," or perfect combination of enhancements that would be great for anyone in any context. For example, night vision may make a person react aversely to strong light or rapid changes in light conditions. Accurate hearing may sound great, but may cause stress and anxiety in loud environments. It is therefore unlikely that everyone will opt to implement the same enhancements.

Is there an intrinsic value in diversity? Some philosophers and bioethicists tend to believe so, and this author is inclined to share that appreciation. Certainly, many opponents of human enhancement fear that human enhancement may bring about the homogenization of the human species (Kass 2002). These authors seem to ascribe intrinsic value to the prevailing level of diversity. However, it is worth reflecting on whether or not mankind happens to find itself at an optimal (from both an intrinsic and instrumental perspective) level of diversity. As this seems unlikely, the intuition that we happen to be at a local optimum with regard to diversity may reflect a status-quo bias, as argued by Nick Bostrom and Toby Ord (Bostrom and Ord 2006). Perhaps *increased* diversity is morally desirable. Sensory enhancement could bring about this diversity.

The Intrinsic Value of Sense Modalities

Amartya Sen and Martha Nussbaum formulated in the 1980s a view of human welfare that has become influential in welfare economics, referred to as the capabilities approach (Sen 1989). According to this view, human welfare is not possible to reduce to subjective well-being, but neither can it be plausibly measured in resources (Sen 1993). Rather, it is what we can accomplish with these resources that matters. According to the capabilities approach, there are some functional capabilities that are good for the person who has them, and people deprived from these capabilities are worse off even when the deprived person does not want or cannot imagine having these capabilities. Imagine, for example, a slave working in a mud brick factory. This person may believe that it would be bad for him or her to be able to read. This does not make the slave less deprived, according to the defendants of this view (Nussbaum 2000). Functioning includes bodily health, bodily integrity, and being able to use one's senses and so on (Sen 1993). Could this framework be extended to include human enhancement? Although this is not what the proponents of the capabilities approach intended, the definition of "normal" health, perceptual ability, and limb functionality seems to be highly context-sensitive. In modern welfare-states, it is a sign of deprivation to lack teeth in one's late fifties, something that was normal 100 years ago. Are we in a similar sense deprived because we lack the sensory modalities that might be available to future generations? If the capabilities approach is correct, the mere fact that we do not regret lacking night vision does not imply that we are not deprived.

Conclusion

Sensory enhancement has long been neglected in the debate on human enhancement. This chapter has argued that sensory enhancement matters and that there are reasons to allow people to experiment with it. Since the technological feasibility of some sensory enhancements is quite tangible, and that the first sensory enhancement devices may reach the mass market in only a few years, there is an evident need for a discussion on the normative issues involved.

Abstract

Stem cell implantation, brain tissue transplantation, and gene therapy for the brain share a common feature. On the one hand, they are seen as potentially beneficial in the quest to cure neurological disorders; on the other hand, ethicists and the public have concern about these interventions affecting a person's identity. This section introduction addresses the rationale behind these concerns and further ethical issues related to intracerebral cellular or genetic interventions. It provides a springboard for the following chapters by Christian Lenk, Heiner Fangerau and Norbert Paul.

Introduction: Identity

Stem cell implantation, brain tissue transplantation, and gene therapy for the brain share a common feature. On the one hand, they are seen as potentially beneficial in the quest to cure neurological disorders; on the other hand, ethicists and the public have concern about these interventions affecting a person's identity. This would be true if the brain is viewed as an organic correlate or the seat of one's identity.

J. Clausen, N. Levy (eds.), *Handbook of Neuroethics*,
DOI 10.1007/978-94-007-4707-4_52,

Basic theories of identity in this context encompass the biological, psychological, and narrative aspects of identity. The theories focus on the biological organism, psychological continuity, and the connectedness and incorporation of experiences into personal history (for an overview, see Shoemaker 2012. For implications of identity concepts on associated fields of interest like the evaluation of human-animal chimeras, see Badura-Lotter and Fangerau 2014). There is concern that stem cells, genetically altered cells, or gene carriers inserted into the brain could interact with native brain cells in a way that fundamentally alters the person's identity. Furthermore, these changes could be irreversible due to the nature of the transplanted cells or genetic modifications. Changes in identity might ultimately be seen as harmful because they essentially represent the end of the original person (Goldstein 2013). This raises significant questions of whether it is morally acceptable to attempt these types of therapies.

The assumed alterations to a person's identity must be examined to determine if these therapies comply with ethical principles in medicine like beneficence and non-maleficence. The target diseases for these therapies are mostly degenerative neurological diseases or diseases resulting in loss of brain tissue such as Parkinson's disease, stroke, different types of dementia, or even psychiatric disorders. Because these diseases can produce personality changes themselves, personality change following treatment is not generally thought to be harmful (Goldstein 2013). To what extent personality changes are acceptable to patients and their families and how severe they would need to be before they would be considered fundamental changes to the patient's identity need to be investigated.

Intention, Control and Ontological Questions

Additionally, the intentions behind stem cell or gene therapies should be evaluated from a moral perspective. The public generally accepts therapeutic testing with the intention to treat diseases. However, testing to simply satisfy curiosity, enhance reputation, or make money is viewed negatively. Therefore, scientific publications on transplanting brain tissue or stem cells have emphasized the therapeutic intentions of authors. The respective scientists aim to develop regenerative therapies for replacement or regeneration of neural tissue. Their reasoning is based on a mechanistic conception of medicine in general and brain physiology in particular (Fangerau 2011). Furthermore, their reasoning is based on the idea that they can control the consequences of their therapeutic actions. The need to control therapies is linked to this understanding of causal therapies. If transplanted stem cells could be restrained and controlled to only act as "pumps" that secrete growth factors to enhance regeneration of endogenous cells or supplement neurotransmitters, they may be viewed differently than transplanted cells that can connect or interact with, invade, or possibly overtake the original brain cells (Fangerau and Trapp 2011). Controllable transplants can be removed if necessary and possible harmful effects can be limited. Uncontrollable cell transplants run risks of growing in unrestrained

ways that would lead to unforeseen, lasting, and progressive complications. The inability to control transplants has proven to be a real danger in the past. As a consequence intention and controllability have become interconnected touchstones in the ethical debates surrounding neuro-regeneration and neurogenetics.

Additional ethical issues exist with stem cell transplantation and gene therapy in the brain. Besides the general consideration about interfering with the personality of the patient, the ontological status of the transplanted tissue is of moral relevance. Some transplants originate from human embryonic tissue. This has generated significant debate over the moral legitimacy of utilizing potential human life to developing cures and the possibility of promoting abortion (see ▶ Chap. 53, "Neural Transplantation and Medical Ethics: A Contemporary History of Moral Concerns Regarding Cerebral Stem Cell and Gene Therapy" by Fangerau and Paul). The status of the transplanted or genetically altered cell should also be considered. Appropriate ethical evaluation requires classifying transplanted tissues as parasitic (they take over the host brain), symbiotic (they cooperate with the host brain), or autonomous (they behave both ways) (Bührle 2011). If potential therapies are to be tested in animals before they are used in human clinical trials (a contested issue itself; see Mauron and Hurst 2011), then implanting human brain cells and of human genes in animals creates chimeras and challenges ethical values like species integrity and human dignity (Clausen 2011). Also, testing novel neuronal stem cell and gene therapies in animals has been debated since the inception of the idea. Finally, fears about the lack of control over therapies after administration have raised questions about research ethics and the potential abuse of study subjects, especially, because potential subjects for human trials might be unable to provide full informed consent to studies if they suffer from degenerative neurological diseases and have reduced cognitive function. General issues like sham surgeries or the use of placebos should be considered with novel intracerebral interventions as well.

Conclusion and Future Directions

The following chapters by Christian Lenk, Norbert Paul, and Heiner Fangerau address these issues in depth and discuss the relatively short history of these two types of intracerebral therapies along with the basic moral values in medicine that they challenge. Ultimately, evaluating the risks and benefits of these therapies will have to consider previous evidence and fundamental aspects of the brain, mind, and identity to understand the ethical challenges that each presents.

Neural Transplantation and Medical Ethics: A Contemporary History of Moral Concerns Regarding Cerebral Stem Cell and Gene Therapy

53

Heiner Fangerau and Norbert W. Paul

Contents

Abstract

The possibilities of brain transplantation, neural transplants, and neural grafting as well as early approaches of gene therapies have inspired the fantasies and optimism of both scientists and the public. They have also caused hopes and fears at the same time, which are reflected in ethical debates about their use and usefulness in medicine. Based on the scientific and public discourse about neural transplants and genetic interventions in a broad understanding, the aim of this chapter is to reconstruct the major aspects of the development of a medical technology and the ethical concerns, which have accompanied its application since the 1890s. Ethical debates may vary in different countries based on different cultures and traditions. Therefore, we must stress that the main focus of this chapter is based on the English and German literature.

Introduction: The Dystopia of Brain Transplantation

The term "neural transplantation" covers a wide range of possible applications within the brain. Complete brain transplantations, homoplastic replantation, transplantation of parts of the brain, brain cell transfer, transfer of genetically manipulated cells, the implantation of fetal neural tissue, and intracerebral stem cell application are covered by this term. Over the course of history, a great variety of methods for interfering with the brain at a cell based level have been used. A comprehensive review by Gopal Das described the replantation of adult neural tissue, implantation of fragments of peripheral nerves, implantation of spinal ganglia, transplantation of nonneural tissue, implantation of tumors, and transplantation of embryonic neural tissue as methods that have been explored between 1890 and 1990 (Das 1990). However, until the late 1980s, the public only seemed to have substantial reactions to reports of complete brain transplantations or brain grafting, which could be interpreted as a major step toward routine brain transplantations, or to put it differently, body transplantations, if the brain is conceived as the host of the "self."

At the time, skepticism was rampant and the horrifying aspects of changing a person's self by transplanting the brain was a timely topic of discussion. At its best, this combination of concerns was reflected in a newspaper caricature, which was possibly triggered by Gilman Thompson's report on "successful brain grafting" in 1890 after he had transplanted pieces of cortical tissue from adult dogs and cats into the brains of recipient dogs in order to test the vitality of transplanted neural tissue in a series of experiments (Thompson 1890). Thompson's goal was not to reconstruct damaged brains, but rather to test the degeneration of brain cells under foreign conditions following evolutionary concepts of the atrophy of non-used organs. While Thompson himself and the reception of his experiments in the journal *Science* was cautious with regard to the practical value (Anonymous 1890), other reactions to his findings reinterpreted or exaggerated the goals and outcomes of his experiments. In an article in the New York Times from 1891 under the heading "Brain Transplantation," the author recounts a conversation with an "amateur professor" who describes how he had performed an experiment in Germany as a "student under Haeckel" during which he had interchanged the cerebellums of a "Dachshund of the sort that Prince Bismarck is so fond of and an enormous tom cat" (J. D. 1891). In a satirical manner, the professor describes his experience in semi-medical terms and in the style of a journal article of that time using the tunneled perspective of an experimenter ("... made an incision in the occiput of each, after both had been carefully washed in a weak solution of bichloride of mercury to prevent any harm being done by noxious bacilli, bacteria, and such things..."). At the end of the story, which is full of references to German names, terms, and stereotypes, the dog behaves like a cat and the cat behaves like a dog. After both animals were sacrificed, the experiment was successfully repeated by exchanging the cerebrums. Without mentioning Thompson and his experiments directly, this article reflects the public reception of his studies: On one hand, the author appears very skeptical with regard to their outcome, as the fictional story

clearly states the perceived implausibility of successful brain grafting; on the other hand the author raises fears providing fictional consequences for the “self” of the cat and the dog, as both changed their behavior according to the brain and not their body. The story is settled in a German experimental context of the late 1890s with clear references to horror stories about the new science of experimental physiology in the style of Marry Shelley’s Frankenstein.

This idea of neighboring brain transplantations with Dr. Frankenstein’s artificial creation of life survived throughout the twentieth century. During the late 1960s, the neurosurgeon Robert J. White reported to have transplanted monkey heads (and brains) to monkey bodies, and in the late 1970s, he postulated on performing these procedures in humans. Because of these experiments, which were broadcasted on German television, the media called him “Frankenstein of Ohio” (Anonymous 1976), a recurrent motif in any discussion about brain transplantation since then (and before). White himself also referred to Frankenstein in an article from 1992 when he criticized the transplantation of human fetal brain tissue into the brains of patients suffering from Parkinson’s disease in order to cure their disorder. He was not only skeptical about the possible clinical results, but he also disapproved of the killing of fetuses for harvesting fetal brain tissue (White 1992). By that time, however, White’s experiments did not form part of the scientific discourse any longer. They were only remembered in news magazines or online news as horrifying stories of the past (Widmann 2000) and “scientifically misleading” (Anonymous 2001).

The Use of Fetal Tissue

While complete brain transplantations remained science fiction through the twentieth century, as the heart surgeon Christian Barnard claimed according to newspaper reports in 1968 (“I do not think a head or brain transplant is possible in our lifetime or even the lifetime of our children”) (Anonymous 1968), the use of fetal brain tissue for brain transplants in order to cure Parkinson’s disease started to become a reality in the 1980s. This “‘modern era’ of brain tissue transplantation,” as the neuropsychologist William Freed put it (Freed 2000, p. 32), not only changed the prospect of neural transplantation toward the hope for regular clinical application, but also brought about a new ethical debate of a different quality that added to the question of the “self” in brain transplantation questions surrounding the use of fetuses and clinical trials with neural tissue.

After an initial peak of interest in various neural tissue transplantation types in the late nineteenth and early twentieth centuries, only sporadic papers had been published on this issue. Between 1946 and the late 1970s, the Science Citation Index lists less than a handful of papers per year on the topic. However, in the late 1970s and especially after 1982, this field of medical research experienced a renaissance, which Gopal Das called a “mushrooming of research activity” (Das 1990). The frequency of reports on successful grafts of various kinds accelerated. The early 1980s can be considered as a watershed, when Low et al.

published a paper in *Nature* in 1982 on "Functional recovery following neural transplantation of embryonic septal nuclei in adult rats with septohippocampal lesions" (Low et al. 1982), which in the media was seen as a promising starting point for "Transplant hopes for brain tissue" (Anonymous 1982). That same year, Backlund et al. were experimenting with the transplantation of material from the adrenal medulla of patients suffering from Morbus Parkinson into their caudate nucleus, hoping that the dopamine produced by this tissue might improve the symptoms of the disorder (Backlund et al. 1985). While studies in rodents using fetal tissue initiated a research surge that promoted the use of fetal tissue as an almost ideal material for therapeutically intended brain transplants, the studies on autografts with adrenal tissue opened the frontier of clinical trials using brain transplants in patients. Fetal tissue grafting was seen as a promising approach, because fetal tissue lacked "extensive neural processes," was "less susceptible to anoxia than adult animal neurons," maintained viability after cryopreservation, making it easier to store, lacked "major histocompatibility complex (MHC) surface markers, offering relative protection to immunologic rejection," and was "capable of producing a number of trophic factors, which may preclude the need for cografting" (Boyer and Bakay 1995, p. 116).

From Bench to Bedside?

While some public media such as the *Economist* remained cautious at first regarding the therapeutic prospects of these studies, it did not take long until the first clinical trials were performed during which patients received fetal allografts. Quoting the above mentioned rodent experimentalists, the *Economist* stated "that much remains to be done before human brain transplants can become accepted therapy" (Anonymous 1983, p. 86). However, after a limited number of studies with medullary autografts during the late 1980s, the early 1990s saw a reasonable number of reports on neural transplants in humans using fetal material (Boyer and Bakay 1995), and scientists were pushing neural transplantation as an established field of research that needed to be translated into practical therapeutic medicine as a remedy for various degenerative disorders.

Overviews of the history of neural transplantation have been published by well-informed experimentalists and specialists of the field (Gash 1984; Björklund and Stenevi 1985a; Gash et al. 1985; Borges 1988; Das 1990). With the help of these articles, the authors created a narrative of a research tradition that has more or less moved in a straight direction forward from Thompson's first reports mentioned above until the research of that time (occasionally literally in a timetable), sometimes explicitly excluding studies by Robert White (Freed 2000, p. 38). These authors placed themselves and their research in a serious tradition of experimental work, which they used to challenge reports by surgeons like White as not serious and sensation-seeking. During this time, several monographs on neural grafting and transplantation were published, including conference proceedings and other edited volumes (Wallace and Das 1983; Björklund and Stenevi 1985b; Das 1986; Gash and

Sladek 1988; Lindvall et al. 1991; Dunnett 1992). Following the concept of Ludwik Fleck regarding the manifestation of knowledge, during these years, the practice of brain transplantation was shifted by protagonists from the level of a new research frontier in journal literature to the more general knowledge of textbooks (for an overview see Martin and Fangerau 2006). A second wave of published textbooks followed at the end of the 1990s, which represented the "decade of the brain" as termed by the US Congress for the period from 1990 to 1999 as an endeavor "to enhance public awareness of the benefits to be derived from brain research" (Jones and Mendell 1999).

Ironically, neurosurgeons had started to hint at the clinical potential of this new research shortly after 1982. From the perspective of sociology, their appeal to the neurosurgical community to participate in this new field of research and application might have been triggered by the perception that the first promising experiments had been performed by a team of physiologists and psychologists. Now, it was felt that the clinical application should be handed over to neurosurgeons. As early as 1983, the official journal of the Congress of Neurological Surgeons, *Neurosurgery*, published a paper by neurosurgeon James E. Wilberger on the "Transplantation of Central Nervous Tissue" in which he repeatedly stated that "although the majority of research in CNS transplantation" was in the hands of neurobiologists, "the information generated thus far is closely approaching the point of making CNS transplantation a clinical tool for the hands of the neurosurgeon" (Wilberger 1983, p. 93). Similarly, seven years before his critical remarks about the use of fetal tissue, the notorious Robert White had expressed his hope in an editorial to the journal *Surgical Neurology* that the neurosurgical community would actively participate in this expanding field and be involved in a "new dimension of neurosurgery," "if and when this intriguing and fascinating line of neurological investigation becomes of human significance" (White 1985).

Early Genetic Interventions into the Brain as a Stairway to a New Paradigm of Control

It was also in the late 1970s and 1980s, when the rise of novel technologies for the manipulation of genes, especially the introduction of restriction enzymes and recombinant DNA, paved the road toward genetic interventions into the human brain. Historically and systematically, genetic interventions were developed along the routes of cancer research and molecular biology. At the same time, environmental, viral, and genetic paradigms used to explain cancer were amalgamated in the "unifying pathway of cancerous growth" (Fujimura 1992) after Bishop and Varmus developed and popularized the so-called oncogene paradigm (Bishop 1982), translating former models of carcinogenesis into cancer genetics. Gene therapy came into sight as a tool to correct cancerous growth by inserting corrective genetic material into cells and tissues which lost their ability to counterbalance the proto-oncogenic potential which was now understood to be part of the genetic inventory of every "normal" cell. Four major obstacles had to be overcome in order

to come to grips with the concept of gene therapy: (1) identification of the dysfunctional gene(s); (2) targeting of those genes with corrective material; (3) integration of the corrective genetic material in the affected cells or tissues; (4) controlled expression of the corrective genes in order to contribute to "normal" cellular behavior. Against this background, it is understandable, why first protocols for gene therapy were dealing with diseases of the blood. The targeting of cells in the blood by simply infusing corrective materials – with or without lipid-packaging or viral vectors – was certainly more easily accomplished than the targeting of cells in tissues like those of the central nervous system.

First attempts of gene therapy resulted in public concern, such as the controversial experiments of Martin Cline who treated patients with beta-thalassemia in non-authorized clinical trial in 1980 and was persuaded to resign from his position at UCLA after the experiment went public. This first episode of gene therapy highlights the ethical and regulatory uncertainties at the biomedical frontier and as a reaction, first regulations with regard to clinical trials involving recombinant genetic materials were put into place in the United States in 1985, when the National Institutes of Health issued guidelines particularly addressing the issue of genetic alteration. Gene therapy, which was regarded to be too premature for clinical trials, was brought back from bed to bench-side. This resulted in a situation in which the flourishing basic research was more and more regulated, but neither regulators nor the public were prepared for the recurrence of gene therapy. This first successful gene therapy was performed in a young girl suffering from a congenital severe combined immune deficiency (ADA-SCID). The protocol was presented and debated in numerous public hearings and ethics committees and the editor in chief of the just founded journal "Human Gene Therapy" French Anderson resumed "And yet, in spite of all this media attention, a considerable portion of the public, including large segments of the medical and scientific communities, did not really believe that an approved clinical attempt at gene therapy was going to take place for, perhaps, years. After the protocol was initiated and the gene-corrected cells were infused into the patient, the question we were asked over and over was: How did this happen so unexpectedly? The answer is, that society had simply not come to terms with the concept that genetic engineering was ready to begin" (Anderson 1990, p. 371f.)

As a consequence, the US authorities decided to establish a more standardized procedure for the evaluation of basic and clinical research dealing with recombinant genetic material. However, the system which included the reactivation of the recombinant advisory committee (RAC) established by the NIH in 1974 as a reaction to public concerns regarding the proliferation of recombinant materials into the natural environment failed its test when the first clinical application of gene therapy into the human brain was performed:

In 1992, the 52-year-old Clemma Hewitt in San Diego, California, was diagnosed with a glioblastoma, a malignancy of the human brain. After surgical intervention, radiation and chemotherapy, and an experimental approach using radioactive antibodies, the patient had to undergo surgical revision because of a recrudescence of the tumor. At this time, the University of California San Diego was developing a therapy based on altered DNA of the tumor itself, that is, the direct application of

recombinant DNA in proliferative tissue to induce "cellular suicide." This experimental approach was far from a clinical protocol, which would have passed the authorities. The physician of the patient, influential Ivor Royston, addressed the NIH using political pressure so that Officials at the National Institutes of Health waived the usual reviews for the new treatment for her. Researchers genetically altered Mrs. Hewitt's own tumor cells to give them a gene for interleukin-2, a substance involved in the production of white blood cells. Her doctors hoped that the altered cells would produce a type of white blood cell that would attack the cancer.

This brief narrative illustrates at least two aspects: First, genetic interventions into the brain were regarded as a last resort applicable in a compassionate release of an experimental protocol with reasonable shortcomings regarding the proof of safety, specificity, and efficacy. Second, the fact that the procedure of compassionate release of premature clinical protocols was established as a standard exception at the NIH in 1993 based on the Clemma Hewitt case might be indicative for the fact that again, neither the scientific community, the medical field, the authorities, nor the public had "come to terms with the concept" that the application of recombinant genetic material into the human brain was ready to begin (Paul 2003).

Long since, genetic modifications not only target malignant growth in the human brain but venture into spheres where cognition and its biological basis in the human brain are inextricably intertwined. A number of studies addressed specific clinical phenotypes and the potential not only to better understand diseases like Alzheimer's disease based on genetics and genomics, but also target or prevent the disease by genetic alteration (Carlson et al. 1997).

Ethical Considerations Regarding Human Brain Grafting

Similarly, skepticism and ethical concerns regarding human brain grafting with fetal tissue were significantly articulated, especially after the human significance of these approaches had vehemently come into sight or had already become reality. For example, Karen Morrison raised some severe ethical considerations in a careful review of the state of the art of brain transplantation, in which she referred to Backlund's experiments, explained the techniques of implanting cells, described the limited primate experiments, and discussed both the realm of connected therapeutic strategies as well as the point of intervention (at an earlier or later stage of Parkinson's disease, for example). Under the heading "Brain transplantation – still fantasy?" she asked (in the order of appearance) whether there was a "moral distinction ... between fetal pancreatic transplantation and fetal brain transplantation," whether there was "enough yet known about transplantation in primates to proceed to human trials," whether therapeutic trials were ethical, whether "moral issues implicit in using fetal tissue" could be avoided using donor tissues "obtained by patient consent" and finally, which "profound ethical questions" were raised by using cross-species grafting (Morrison 1987, p. 443). Without delving deeper into these moral issues, Morrison fully captured most of the ethical issues that would be subsequently discussed in the following years with regard to brain grafting with fetal tissue as well as stem cell implantation after the year 2000.

On a more abstract level, these issues also included the question of possible alteration of personal identity by transplants, the formation of chimera, and the instrumentalization of human embryos. In addition, the justification of clinical trials was questioned due to the lack of sufficient animal experimentation and sufficient evidence of efficacy as well as limited controllability and minimal reversibility. The question of altering the human mind and personal identity by transplantation and of the ethics of species hybridization mainly remained theoretical during the early 1990s and again in connection with stem cell research after 2000 (Greene et al. 2005; Berg 2006; Wade 2005). They were mostly treated in the form of in thought experiments. However, the problems of embryo instrumentalization and experiments in humans gained practical importance very early on in the debate. In particular, the practical use of embryonic tissue raised concerns (Jones 1991). While scientists and some bioethicists had been quick to conclude "that retrieval of such tissue from fetal remains is analogous to the transplantation of organs or tissue obtained from adult human cadavers" (Mahowald et al. 1987), the question of the origin of this tissue raised concerns about induced abortions.

In the United States, these morally driven reactions had real consequences for scientists in the form of ethically based research restrictions at the end of the 1980s. When in 1987 a researcher proposed a research protocol to the National Institute of Neurological Disorders and Stroke (NINDS) in which he suggested to implant fetal neural tissue harvested after induced abortions into the brains of patients suffering from Parkinson's disease, the director of the NINDS passed it on to the director of the National Institutes of Health (NIH) to have it approved. The Institutional Review Board had not raised objections to the proposal, but the director of the NINDS had considered the protocol ethically critical enough to have it consented by the director. The director in turn sought advice from the United States Department of Health and Human Services (DHHS) (a cabinet department of the national government). As a consequence, the Assistant Secretary for Health issued a moratorium that stopped financial support from public federal sources for transplantation research using fetal tissue from induced abortions and established an advisory committee that was charged with discussing the controversial ethical issues (U.S. Congress 1990, p. 171; Hoffer and Olson 1991). Although the advisory board agreed that research with fetal tissue should be allowed under certain conditions, the ban was not lifted until 1993 by the then new Clinton administration (Clinton 1994). The moratorium had been under constant attack, because it was said to hinder research and possible cures for patients in the United States, while in "the meantime other countries, Sweden and Canada in particular, are making headway" (Beardsley 1990). Critics of the research ban conducted questionnaire surveys that were intended to research public attitudes regarding the ban, and concluded that "at least among psychology students, there is a favourable attitude to research on and clinical use of fetal neural tissue" (Sanberg 1990). At the same time, other authors articulated severe moral concerns regarding the use of induced abortions for gaining fetal transplants (McCullagh 1988). They saw abortion either as immoral *per se* or warned against the instrumentalization of possible life, fearing that women might become pregnant and donate their aborted fetuses without clear consent, or that (in line with the quoted

questionnaire survey) abortion would become socially acceptable if it was concomitantly connected to curing neurological diseases (Jones 1991; Coutts 1993). Thus, as a compromise, it was suggested that restrictions were needed "to prevent the use of grafts from encouraging induced abortions and to maintain high standards of respect for life and human dignity," but if these restrictions were enabled, then the use of fetal tissue to possibly cure disease could not be objected to anymore (Boer 1994, 1999). The hope and promise to find cures has been a strong argument for justifying morally ambiguous regeneration research before, and therefore, it is not surprising that this argument was also discussed and challenged in the discourse about neural transplantation. In addition, regeneration scientists tried to suggest technological solutions for moral objections (Fangerau 2011).

In a special issue of *Trends in Neurosciences* in 1991, Olle Lindvall explained the prospects of neural transplants in human neurodegenerative diseases such as Parkinson's, Huntington's, dementia, amyotrophic lateral sclerosis, and hereditary ataxia. He had been one of the first scientists who grafted tissue from the ventral mesencephalon of human fetuses to the brains of patients suffering from Parkinson's disease using a stereotactical method, but nevertheless, he carefully avoided calling neural transplantation a panacea in this article. While answering criticisms regarding the state and security of the technology as well as the associated fears to "try" an immature therapy that was possibly connected to neuroblastoma and behavioral changes in patients (Moss and Rosene 1985; Rogers et al. 1985), he maintained that neural grafting was still in its infancy and that clinical trials in a few, optimally selected patients would be necessary in the future. Like other careful authors of the period, he seems to have followed an ethical discourse brought up repeatedly in the discussion about neural transplantation on the ethics of communicating research results, which recommended not raising unrealistic hopes in patients by prematurely reporting results (Morrison 1987; McCullagh 1988; Rehncrona 1997). Thus, for Lindvall, only the "lack of adequate medical therapy" and the "severity of symptoms in these disorders" legitimized further research and clinical studies in patients, although the procedures in question had not been optimized before in animal experiments, just as it had been the case with premature protocols of gene therapy. In addition, he recommended that encapsulated cell lines or genetically engineered cells should be used for neural transplantation instead of fetal tissue. If cell transplantation was to become a routine clinical procedure in the future, then more donors for the controversial material from aborted human fetuses would be needed and the source of human material itself would be unavailable in some countries (Lindvall 1991).

Ten years later, stem cells seemed to provide a means to settle at least some ethical concerns, although they were also disputed as problematic because of their embryological origin. However, in the eyes of some ethicists, lawyers, and scientists, "the promise of stem cell research for millions of patients" and the different characteristics of stem cells making them less connected to abortion justified their use for therapeutic purposes. In line with the tradition of neural transplantation, "medical progress" was offered as a multi-tool offering at the same time therapeutic hope and a technological fix for ethical concerns (Annas et al. 1999; Merkel et al. 2007, p. 115).

Despite the argument of research offering hope, the problem of the justification of clinical trials in patients remained. It was (and still is (Hess 2012)) disputed as to which patients and under which risk-benefit ratios experimental intracerebral interventions are morally acceptable. Groups such as the "Network of European CNS Transplantation and Restoration," which besides technical aspects also addressed ethical issues (Hoffer and Olson 1991), formulated protocols for operation procedures and recommendations for trial protocols and patient selection. Major moral issues revolved around the irreversibility or only the partial reversibility of neural grafting and gene therapy in the brain. In addition, the question was under discussion of whether sham surgery was acceptable or not, because among other arguments, it was disputed as to whether proper informed consent for sham surgery was possible at all (Merkel et al. 2007, pp. 83–91). Finally, the debate regarding trials in patients was influenced by fears and a lack of knowledge of possible personality changes that could occur as a result of the procedure.

Although Merkel et al. retrospectively regarded the debate about personality changes as "erroneously brought up" (Merkel et al. 2007, p. 104), neural transplantation and gene therapies of the brain had been accompanied by a differentiated philosophical debate about possible changes of personality and identity (Gillon 1996; Northoff 1996; Burd et al. 1998), which has been repeated in the context of stem cell transplantation (Grisolia 2002; Goldstein 2013). Based on thought experiments by researchers such as Derek Parfit among others Georg Northoff discussed the arguments of proponents and opponents of the idea that brain transplantation altered the personal identity of a patient (Goldstein 2011). He concluded that both used the same arguments but with "different underlying presuppositions" regarding the meaning of "identity," the definition of brain identity, and the relationship "between mental states, psychological functions, and neurophysiological properties." Therefore, he urged for neurophysiological, clinical, and philosophical evidence to enrich the discussion (Northoff 1996).

Without directly referring to Northoff, Rehcrona provided some of the needed evidence in a critical review published in 1997 on the status of brain transplantation. Rehcrona evaluated the results of human clinical trials that had been performed up until that year. In the review, he considered the risk of a transfer of personality among other aspects, which he "assumed to be nonexistent," because only small tissue parts, limited amounts of material, and above all undifferentiated embryological tissue are transplanted. If personality changes did occur, then he tended to attribute them to the cure of a disease, which had altered a patient's personality before, and if that was the case then he regarded these changes as "goals of the treatment" rather than a "complicating side effect" (Rehncrona 1997, p. 8). However, he took a different stance regarding psychiatric side effects, which had been reported in some studies. In particular, he stated that after open microneurosurgical grafting (different from stereotactical methods), a considerable number of patients suffered from "frontal lobe syndrome," which by definition is characterized by severe changes of personality. Regarding a possible use of neural grafting to treat psychiatric patients, he directly warned against "premature, human experiments with brain tissue grafting . . . to treat psychiatric disorders" and requested

solid scientific data and methods to reduce these associated risks (Rehncrona 1997). After all, the issue of human identity in close connection to neurocentric concepts of cognition and personhood seems to be one of the hinges on which the ethical debate about alterations – be it grafts of genes – of the very "wetware" of our minds is now swinging (DeGrazia 2005).

Concluding Remarks

Rehncrona's paper seems to paradigmatically reflect the discursive field that has shaped the discussion about neural transplantation during the 1990s and stem cell transplantation into the brain during the 2000s. Hope, risk perception, opaque fears, and personal identity were issues directly linked to the manipulation of patients' brains. The source of the material to be transferred (fetal tissue, stem cells) was the associated or even preceding practical problem that brought with it moral implications.

Similar to this interpretation, the analysis by Moreira and Palladino differentiated the regimes of "hope" and "truth" as two crucial and interdependent tropes of the discourse in the 1990s and early 2000s about treating patients suffering from Parkinson's disease with the help of neurotransplantation. According to their view, the regime of hope justifies experimental and therapeutic endeavors with the promise of what could be, while the regime of truth rather "entails an investment in what is positively known" (Moreira and Palladino 2005, p. 67). While the regime of hope considers the patient as someone waiting for new solutions, the regime of truth sees the patient as someone who evaluates approaches according to risks, effectiveness, and costs. In the debate about neuroimplantation, these regimes rely on each other in "mutual parasitism" (Moreira and Palladino 2005, p. 73), because hope in what could be can only rely on what is positively known so far, and further gains of knowledge rely on hope for the better, because "truth" requires future experiments triggered by hope as a resource of evidence. A point of reference for both regimes in the neuroimplantation debate is seen by Moreira and Palladino in the "self," which shall either be recovered by the therapies in question under the regime of truth or relaunched as a "new self" emerging from neurophysiological dynamics under the regime of hope (Moreira and Palladino 2005, p. 74).

Robert White's experiments of the late 1960s did not offer much hope, and their truth in the form of medical value was questioned by medical scientists (Freed 2000). Thus, his sensational reports were subsequently only discussed in news magazines as frightening Frankenstein stories after the 1980s. The other forms of neural transplantation discussed here, however, were able to bring the regimes of hope and truth together at the same time. While some moral issues, such as the use of fetal material, could be seemingly fixed technologically (the technological fix is problematic under some perspectives, because the technology per se is not discussed (Fangerau 2011)), other moral issues revolving around hope and truth, risk and fear, and prospects for personal identity could not be fixed and are debated in other chapters of this handbook.

Gene Therapy and the Brain

54

Christian Lenk

Contents

Abstract

The chapter examines the implications of gene therapy in the human brain from the ethical point of view. In the first part, a number of principles from research ethics are discussed for the field of the neurosciences. While there exists a consensus in the area of medical ethics as a whole, what ethical principles are essential, this is less clear in the specialized field of neuroethics. Therefore, the presentation and discussion of the seven principles has the aim to clarify the normative foundations of the following ethical evaluation of gene therapy in the brain. In the second part, selected studies with clinical applications are presented from the literature and general risks and burdens for participating patients are identified. The literature review shows a participation of vulnerable persons, and the use of sham surgery and randomization for the blinding of studies. The situation of patients with a chronic dementia disease is addressed, and conclusions are derived under an ethical perspective. In this chapter's final section, a short overview is given about the current development of gene therapy from the ethical point of view, and which advances and setbacks seem to be important for the assessment of the research field. Gene therapy for neurological diseases

shows some specific risks and burdens for participating patients. These have to be addressed carefully and systematically to realize adequate research study designs, to avoid misunderstandings on the side of the patients and study participants, and to enable an optimal risk monitoring and risk control in the clinical testing and use of this new therapeutic approach.

Introduction and Basic Ethical Considerations

Before analyzing the field of gene therapy in the brain and the connected ethical questions, from a medical ethics' point of view, it is preferable first to clarify the underlying ethical principles which form the basis of our normative work. This task is not so difficult for the whole field of medical ethics, because there is a kind of consensus that the four-principle approach of Beauchamp and Childress can serve as a starting point for ethical analysis in the medical field. However, despite the fact that the four-principle-approach can give some orientation, it is also true that it is in most cases not sufficient to enable a fully comprehensive understanding of ethical problems. And the normative foundations seem to be even more unclear in the case of neuroethics, because less publications have focused on this issue and at the present point of time, no acceptable consensus has appeared [Insert reference to theoretical articles in the handbook?], what norms and values are decisive for the ethical analysis of neurological problems. Therefore, I want to create something like an ad hoc approach for the analysis in this chapter and discuss some principles of research ethics and neuroethics which were prominent in the previous discussion. A number of these principles are also described in international conventions and declarations, what shows their relevance over and above the narrow field of interest in this chapter. The idea is not to develop at this place a new ethical approach to neuroethics but rather to clarify the normative issues as far as possible before starting to discuss the ethical problems connected with gene therapy and the brain.

The fact that gene therapy is at the present point of time an experimental approach has also some influence on our perception of the field. In the application of an already introduced therapy, there are clear expectations, which proportion of the patients can profit from a specific therapy. Ideally, there are also a number of well-defined criteria which allow identifying those persons of a patient group who will especially profit from this therapy. These expectations are derived from former practical experiences, already conducted clinical studies, and so on. However, the focus in experimental studies is different, due to the fact that there is at the starting point of a clinical trial, no confirmed knowledge regarding the effects of this new therapy. Therefore, the focus in research ethics lies far more on the responsible limitation of risk than on possible benefits for the patients. Strategies of risk limitation comprise, among others, preclinical and animal studies, pharmacological analysis and evaluation, close medical and psychological monitoring of patients during the study, the appropriate choice of the participating patient group, and a rather conservative risk-benefit-analysis. Researchers, physicians, and patients,

especially in the case of dangerous, severe, and chronic diseases, are often enthusiastic when confronted with new research approaches. Research ethics faces here the difficult task to transfer previous experiences and sometimes difficult lessons from research to the clinical practice.

Some Normative Principles for Neuroethics

1. *Every medical intervention must respect the autonomy and dignity of patients.*

   It can count as one of the premises of modern biomedical research, that it has to be in accordance with the patients' autonomy and dignity or that it is otherwise not acceptable. The patients' autonomy has to be guaranteed by the patient's informed consent or the assent of her or his relatives or legal representatives. Despite the mere self-determination of patients through the principle of autonomy (which is materialized in the written consent of the patient), human dignity can be seen as a even wider and more comprehensive ethical demand which (in the Kantian tradition) pronounces a person's intrinsic value and aims to exclude the instrumentalization of persons, i.e., to use somebody "merely as a mean." Therefore, it can also be found in Art. (1) of the CoE Convention on Human Rights and Biomedicine.[1]
2. *The patient's original identity should be preserved or restored in the course of a neurological intervention as far as this is possible.*

   The identity of persons was without doubt one of the central concerns of the previous discussion on neuroethics. Like other medical interventions which aim on the restoration of an original (healthy) state, for example, the treatment of demented patients in neurology aims also on a kind of restoration of an "original" mental state in the sense of "not influenced by disease-related dysfunctions." However, it has to be considered that personal identity is not a static, but a dynamic concept and in the case of neurological diseases, that the personal identity can also be influenced by nonreversible pathological developments. However, from my point of view, it is a clear implication of neurological *therapy*, that it is in general not the aim of such a therapy to create a person with a new or changed identity but to preserve and restore somebody's original identity as far as this is possible (in the sense of a *restitutio ad integrum*). These short descriptions already show that there is an urgent need for more theoretical considerations in neuroethics concerning this important but very complex issue.
3. *Research interventions in competent persons are from the ethical point of view preferable in comparison to interventions in noncompetent persons. Research interventions in noncompetent persons are only acceptable with a high probability to realize a significant health benefit for the concerned person.*

[1]"Parties to this Convention shall protect the dignity and identity of all human beings and guarantee everyone, without discrimination, respect for their integrity and other rights and fundamental freedoms with regard to the application of biology and medicine. Each Party shall take in its internal law the necessary measures to give effect to the provisions of this Convention."

Accordingly, the Council of Europe's Convention on Human Rights and Biomedicine, foresees in Art. (17), 1 that:

> Research on a person without the capacity to consent [. . .] may be undertaken only if all the following conditions are met:[. . .]ii. the results of the research have the potential to produce real and direct benefit to his or her health;iii. research of comparable effectiveness cannot be carried out on individuals capable of giving consent; [. . .]v. the person concerned does not object.

Following the Convention, an exception to this rule is only given, when "the research entails only minimal risk and minimal burden for the individual" and the research contributes to the scientific understanding of the concerned persons' or comparable persons' condition. The Convention's additional protocol on biomedical research concretizes in Art. (17), 2 that a minimal burden is only a "temporary and very slight [discomfort]." In another document, the EU Ad Hoc Group (2008) names for the pediatric population a quality-of-life assessment or blood pressure monitoring as examples for a "minimal risk."

4. *In medical research in general and experimental settings in particular, the potential therapeutic benefits of neurological interventions have to be weighed very carefully against possible risks and adverse events.*

   May be, one could call this clause also the "proportionality principle" of research ethics.[2] This principle can be found in most documents on the correct ethical and legal conduct of research in humans. Art. (16) of the Declaration of Helsinki foresees that "Medical research involving human subjects may only be conducted if the importance of the objective outweighs the risks and burdens to the research subjects." Comparably, the Oviedo Convention from the Council of Europe demands in Art. (16): "Research on a person may only be undertaken if all the following conditions are met: [. . .] (ii) the risks which may be incurred by that person are not disproportionate to the potential benefits of the research; [. . .]" Given that the exact possible benefits of gene therapy in the brain are at the present point of time still unclear, every effort should be undertaken to properly assess and minimize possible risks for the participating patients.

5. *Reversible interventions are preferable to irreversible interventions.*

   A concern which is frequently articulated in the context of innovative and experimental methods is that irreversible interventions should only be undertaken at a point of time when reversible interventions have shown not to be effective. The idea behind this principle is that reversible interventions could ideally be made undone, but that irreversible interventions will accompany the patient far into the future. Therefore, the reversible intervention should be preferred in such a situation. For example, one would prefer in a specific patient group as a first-line treatment an established medication before implanting a medical device for deep brain stimulation. However, also electrodes for deep brain stimulation are rather reversible like older forms of neurosurgery which

[2]For a comprehensive and current overview on proportionality in research ethics, cf. Hermerén (2012).

were definitely irreversible. But one has also to consider that the human body has no mere modular structure and that also the extraction of medical devices from the body can bear a significant burden and risk for the concerned patient.

6. *In neurosurgical interventions, not only the direct and short-time consequences should be documented, but there should also be a systematic plan to document and evaluate the long-time effects on the patients' health, personality, and quality of life.*

   It is a known claim in clinical studies which aim on the approval of a new drug that the application of this drug should also be further observed in clinical practice. For example, in an approval study, the patient population is often different from the patients who will receive the drug finally in medical practice. Additionally, it is not known whether the first studies with a drug are sufficient to document all possible side effects. For example, a long-term study revealed in 2004 that the analgesic Vioxx had unacceptable side effects for the patients. Neurosurgical and genetic interventions into the brain should also be reassessed by such long-term observational studies.

7. *The introduction of experimental approaches should take place very carefully, only in small steps, and only after the sufficient preparation by preclinical and animal studies.*

   Insofar gene therapy in the human brain is a new and experimental therapeutic approach with no known predecessors, research in human beings has to be prepared by animal studies, and it has to be started only in small numbers in specially selected patient populations. On the one hand, patients should be able to give their informed consent and should already show manifest signs of disease; on the other hand, experimental therapies with critically ill patients in the last stages of their life have to be seen as problematic. It seems to be more appropriate for experimental tests of fully new therapeutic approaches to start clinical studies with patients in a stable health state and a maximum of safety measures (careful preclinical and animal tests, low doses for the first clinical studies, close medical and psychological monitoring during tests, and so on).

Genetic Interventions and Connected Risks in Clinical Research Practice

A general ethical assessment of gene therapy in the brain seems to be difficult at the present point of time due to the structure, location, and organization of research. From a short literature review (Berry and Foltynie 2011; Kaplitt et al. 2007; LeWitt et al. 2011), it follows that such studies are currently only organized with rather small patient groups in early study phases which deal with a general proof of principle or the safety and tolerability of the respective therapeutic approach. The different approaches – in relation to the kind of virus for gene transfer and the kind of inserted genes – seem to be rather heterogeneous and diverse. It follows that a comprehensive and concluding discussion of the therapeutic benefit of gene therapy in the brain cannot be done at the moment. But this means also that

a final risk-benefit-analysis, which must always be an essential element of an ethical analysis in research ethics, is difficult at the present point of time. The report of therapeutic effects is in the end – despite the publication of research progresses – rather anecdotal and does not reach the level of reliability, for example, of large clinical drug trials.

In place of an overview of the different therapeutic approaches to a number of disease entities, I will focus in this chapter on the area of gene therapy in the brain which seems to be at the present point of time the most advanced, i.e., therapeutic approaches in Parkinson's disease (PD). Therefore, the above named three studies were selected from the last 5 years which were published in high-profile scientific journals following the hypotheses that ethical questions concerning gene therapy in the brain can be probably identified best in the most advanced cases of a research paradigm. However, it cannot be concluded in any case that it is possible to transfer the findings from this research field to other applications of gene therapy in the brain.

The application of gene therapy in the case of the human brain must produce a number of ethical questions and different kinds of risks due to the combination of different forms of invasive interventions.

Firstly, the current research approaches of gene therapy in the brain need a surgical intervention to bring the therapeutic substances to the place where they are intended to have their therapeutic effect, i.e., into the areas of the brain which are influenced by the pathological processes of the disease. However, such a therapeutic approach then produces an own kind of risk with the one-time or repeated injection of the therapeutic agent into the brain or the implantation of a cannula for the supply of the treated brain areas (with the opening of the skull, the irritation and swelling of tissue, possible infection, and so on).

Secondly, there is the known genuine risk of a gene therapy treatment. In the historic case of a volunteer who died in 1999 as a test person in a Phase 1 dose escalation study concerning ornithine transcarbamylase (OTC) deficiency, the 18-year-old developed a fatal immune response due to the high dose of adenoviral vectors (Kimmelman 2008, p. 242). Immune reactions of study participants in the case of adeno-associated virus (AAV) vectors are also cited in a later gene therapy study (Kaplitt et al. 2007, p. 2097). In 2003, three of the children, who suffered from X-linked severe combined immune deficiency (X-SCID) and were treated with a new gene therapeutic approach at the French Necker Hospital, developed T-cell leukemia (Wood et al. 2006; Zarzer 2006).[3] Further research showed that the leukemia was provoked by the insertion of the changed gene material. The authors of the named articles showed also that this danger could have been identified before the clinical trials when animal tests would have been longer than the 6 months before the actual trial (Wood et al. 2006). The review article of Berry and Foltynie (2011) additionally names antibody formation and cerebellar toxicity in animal

[3]In 2008, Kimmelman reports that this number has later increased to five children with leukemia. (Kimmelman 2008, p. 239).

Table 54.1 Combination of different types of risks in the case of genetic interventions into the brain

Kind of intervention / effect	Possible associated risks
1. Neurosurgical interventions for the transfer of the therapeutic agent into the brain	Irritation and swelling of tissue, possible infection, etc.
2. Genetic intervention (gene expression and gene transport by viruses)	Immune reactions, antibody formation, cerebellar toxicity, cancer, disturbance of dopamine concentration or of other substances
3. Long-term neurological or psychological impact of (2)	Yet not described for genetic interventions into the brain, possible change of personality (see for example the debate on deep brain stimulation)

models (Berry and Foltynie (2011), p. 180), the disturbance of dopamine concentration in the brain (Berry and Foltynie (2011), p. 183), and an "indiscriminate gene expression across all neuronal cells (and/or glial cells)" (Berry and Foltynie (2011), p. 183) as possible adverse events of gene therapy in the case of Parkinson's disease. Kimmelman (2008, p. 239) concludes:

> What distinguishes the risks of somatic gene transfer trials from those for conventional drugs is not so much the level of risk [. . .] but rather their level of complexity and of uncertainty. [. . .] Furthermore, even though numerous trials involving retroviral vectors have been carried out, there is no widely accepted system for quantifying the risks of insertional mutagenesis.

Thirdly, in the case of cerebral interventions and manipulation, a possible change of personality of the treated person is constantly discussed and would conflict with our principle (2) which was described at the start of this article ("*A patient's original identity should be preserved or restored in the course of a neurological intervention as far as this is possible*.") Changes of personality were described for the "classic" neurosurgical interventions like lobotomy in the 1940s and 1950s as well as for the current approaches to treat motoric and psychiatric symptoms, for example, of Parkinson's Disease with deep brain stimulation. It has to be considered that there can be huge differences in the extent of personality changes from the strong and irreversible reduction of personality traits (in the case of lobotomy) to relatively slight and transient hypomanic episodes (in the case of deep brain stimulation). However, it cannot be excluded that changes in personality can also occur in the case of genetic interventions, especially when these – as described in the last paragraph – will influence the biochemical homeostasis of the brain (Table 54.1).

Examples from Current Studies

From the diseases of the brain, Parkinson's disease (PD) seems to be the disease entity which stands at the moment most directly in the focus of gene therapy. The disease manifests relatively lately in life and is in general associated with

movement disorder and tremor, but also with cognitive, emotional, and vegetative changes (Riess et al., A-2739). Pathological research showed that in the brain tissue of concerned patients, the cell death of specific neurons leads to a lack of dopamine in the striatum (a part of the forebrain) which is then (according to this model of disease) seen as the cause of the movement disorder. This part of the brain is in general associated with the so-called executive brain functions which coordinate emotion, cognition, and movement. The frequency of PD is dependent from age and increases from 1.4 % in the group of the 55 years old to 2.0 % at an age of 65 and 3.4 % in the group of the 75-year-old persons (Riess at al., A-2742). Although hereditary forms of PD are known, the majority of cases is multifactorial or polygenic (Riess et al., A-2746). The idea in a number of PD studies based on gene therapy is in general to insert genetic material into the brain cells to increase the dopamine production and therefore to compensate the tissue's lost ability to produce this neurotransmitter.

From medical ethics' point of view, patients with dementia are a group of "vulnerable patients" and their inclusion in medical research needs specific attention and consideration. However, not because of the disease entity itself patients with PD are seen as vulnerable, but because of the possible disease impact on patient autonomy, there may be impaired ability for self-determination, the competence to assess the consequences of possible study participation, and maybe a diminished ability to give informed consent. Therefore, persons in an early phase of the disease may act fully competent while patients in a later phase of the disease may have lost this ability (cf. also Rosenstein and Miller 2008, figure 41.1: 439). In addition to the ethical considerations concerning the treatment of these patients, many national legislations demand the designation of a legal guardian for patients with reduced competence. The Declaration of Helsinki and the Council of Europe's Declaration on Human Rights and Biomedicine both have own paragraphs on medical research with patients who are not fully competent to give informed consent. For the participation of noncompetent participants, in addition to the approval of the legal guardian, the Declaration of Helsinki demands in Art. (28) that:

> These individuals must not be included in a research study that has no likelihood of benefit for them unless it is intended to promote the health of the group represented by the potential subject, the research cannot instead be performed with persons capable of providing informed consent, and the research entails only minimal risk and minimal burden.

In the case of experimental, risky, and invasive treatments (like in the case of gene therapy in the human brain), there is often the consideration that only patients should be included into the study which did not profit from other (for example, pharmaceutical) therapeutic approaches. The rationale behind this procedure is that those who obviously have no further chance of healing in conventional therapeutic regimes should receive a "last chance" to participate in a therapeutic study, even when the probability of a successful outcome might be rather small. But this can lead to the effect that only severely ill (and in the case of PD, noncompetent) patients are included into such a study. However, from my point of view, such an approach should be limited to less experimental therapeutic approaches and, like it

was described above, in the case of gene therapy, only patients in earlier phases of the disease should be included into such studies.

Current research approaches of gene therapy in the case of PD mostly base on the creation of viruses which have the task to bring gene particles into the concerned body region (the brain), where the changed genetic information should get into the defective cells or tissue.

One of the selected studies was a sham-surgery controlled, randomized trial (LeWitt et al. 2011). Sham-surgery control is a procedure where a part of the participating patients does not receive the injection of the therapeutic agent into the brain tissue, but only a placebo. To mask this fact and to enable the so-called blinding of the study, these patients receive the same surgical intervention, but no injection into the brain tissue (although, for example, the noise of the pumps is simulated, and so on; LeWitt et al. 2011, p. 310). Placebo-controlled trials are rather recommended for slighter diseases, where the symptom assessment is also clearly influenced by subjective factors. Due to the severity of the symptoms of PD, it is questionable whether it should be used in the case of this disease.

Sham surgery produces also new risks and burdens for the participating patient group without an individual benefit. The most commonly accepted document of research ethics, the Declaration of Helsinki, does not address the conduct of sham surgery for blinding purposes. However, it is generally presumed that the blinding of a study with the help of placebo (in drug testing) itself does not harm the patient. This is also the reason why severe disease entities are normally not accepted for placebo studies, because the omission of therapy would otherwise provoke further disease progress and therefore a study-related harm of the patient. However, the case is obviously different in case of sham surgery, where the patient carries in any case the burden and possible health risk associated with sham surgery. From my point of view, the possible scientific value does not justify the connected burden and risk for PD patients. Like it was described above, the method of gene transfer bears itself remarkable health risks, and methodological enthusiasm should be rather invested into the development of safer gene transfer than into avant-garde methods of study blinding.

Conclusions

This chapter presented a general overview about the previous developments of gene therapy from the point of view of patient safety and medical ethics. This overview was combined with an analysis of current studies with PD patients of gene therapy in the brain. For both areas, sufficient examples and well-documented studies could be identified for the following conclusions from medical ethics. However, it has to be seen that in comparison to other (i.e., pharmacological) treatment approaches of the disease, the present descriptions and studies of gene therapy in the brain are rather experimental and based on rather small patient groups. Statements on risks and benefits of gene therapy in the brain must therefore remain tentative at the present point of time.

The historical development of gene therapy shows impressive progresses and successes. In a way, it is astonishing that the insertion and expression of therapeutically manipulated gene material into the cells of the human body is possible. However, our analysis showed that the development of gene therapy is accompanied by hard and maybe disastrous setbacks, which caused the death or severe disease of participating patients, who belonged to vulnerable groups like adolescents and children. The medical and ethical discussion after these severe adverse events showed that they would have been in principle avoidable by a more careful study design (i.e., avoidance of dose escalation and longer and more comprehensive animal and preclinical studies). However, because the researchers were not able to foresee the existing problems, these adverse events could not be prevented.

The normative (ethical and legal) evaluation mechanisms and principles have probably to develop together with research in gene therapy and neurology. This is at least a conclusion one can draw from other fields of medical and research ethics, because in most of the research fields, it cannot correctly be anticipated what direction practical research will take and what kind of burdens and risks patients may face with new research approaches and study designs. The existing framework for ethical analysis and evaluation has therefore to be strengthened and systematized to achieve a better consensus about the relevant ethical criteria. In comparison to other fields of medical ethics, the ethical evaluation of gene therapy in the brain as an interdisciplinary area between neurology and gene therapy has at the present point of time to resort to a kind of ad hoc compilation of ethical principles from the previous discussion.

The ethical analysis of gene therapy in the brain in the case of PD patients identified a number of potential risks and burdens for study participants. Firstly, it should be further cleared and discussed, which PD patients should be included into clinical studies. Given that gene therapy comprises more than “minimal risk,” the participants should be able to decide for themselves to give the consent for study participation. Secondly, gene therapy can produce totally different kind of risks (for example, immune responses, increased risk of neoplasia, etc.) which strongly seem to differ between different studies. It follows that there must be an extremely careful case-to-case evaluation of gene therapy studies. Finally, the evaluation of innovative research projects has to a certain degree also to consider the context of these projects, like it is described by Kimmelman (2008, p. 240):

> Many early phase gene-transfer trials bring together a potent mixture of desperately ill research subjects, ambitious (and sometimes financially invested) clinical champions, biotechnology firms, engaged disease advocates and news media. These factors have at times produced a turbulent dynamic in which concepts are rushed into trials, preclinical and clinical results are oversold, research efforts are fragmented and adverse events go underreported.

In principle, research ethics and the existing documents like the Declaration of Helsinki are prepared to deal with these problems. However, a steady and systematic backing of such research projects is necessary not only to realize potential benefits from gene therapy, but to avoid unacceptable risks and burdens for the participating patients.

Ethics in Psychiatry

Ethics in Psychiatry

55

Hanfried Helmchen

Contents

Abstract

Good relationships among people have been stabilized by traditional customs and normative rules that have emerged over long time periods and have been acquired during individual development. These customs were originally supported by religious funding; today however they are mainly based on law and social context. Reflecting on customs and morals, on their rational justification, and on analysis of their problem-related impact is the object of ethics. Ethics in psychiatry deals with the reflection on how general moral norms are applied to specific psychiatric situations,[1] especially by the professional physician acting with the mentally ill patient, e.g., respect for the will of the mentally ill with questionable or lost capacity to consent, or risk-benefit-evaluations.

Ethical Principles

Today **welfare** and **will** of the patient are the dominating principles of the ethical evaluation of medical action. Whereas it is timeless Hippocratic tradition that the

[1] Insofar there is no special psychiatric ethics.

H. Helmchen
Department of Psychiatry & Psychotherapy, Charité – University Medicine Berlin, CBF, Berlin, Germany

DOI 10.1007/978-94-007-4707-4_53,

physician should act exclusively for the welfare and in the best interest of the patient, his obligation to respect the autonomy and dignity of the patient has modern roots in the era of enlightenment (Beauchamp and McCullough 1994).

The latter-mentioned principle achieved outstanding significance during the past decades. This is clearly recognizable in the development of the legal doctrine of **informed consent** (Koch et al. 1996). Its sources, among others, are found, on the one hand, in the shifting of modern medicine from acute to long-term treatments, to risky and burdening treatment measures, to replacement medicine, and even to clinical research, all of which require much more participation and thereby more responsibility of the patient, e.g., for adherence in long-term treatments; on the other hand, civil rights, such as the legally protected self-determination and human dignity, will be increasingly recognized as indicated by the UN Convention on Human Rights of Persons with Disabilities (CRPD 2006). The dignity and autonomy of a patient is the more threatened the more he or she is dependent upon nonself-determined actions by which he or she becomes an object, as is found in modern medicine with its widely regulated courses of action. A reflection on this and a change of professional as well as of societal attitudes towards people with mental illness, i.e., to attenuate discrimination and to enhance self-determination, are currently taking place.

One of the old principles, already stated in the Hippocratic Oath, is that of **nil nocere**, i.e., do not harm. This principle emerged in previous times of a wide lack of therapeutic power and of nonproven therapeutic measures. However today, in view of the risks and unwanted side effects of many contemporary effective diagnostic and therapeutic measures, this principle must be understood as a challenge for a benefit-risk evaluation of each medical intervention. This evaluation, related to the individual patient and put into effect by him- or herself as well, will increasingly be influenced by his or her social and especially economic context.

Example
Many physicians see the efficiency of current antidementive drugs as too low for their application, and accordingly such drugs will not be paid for, e.g., by the National Health Service in the United Kingdom.

Such application of limited resources for the best possible, i.e., evidence-based, help for the largest possible number of ill people will be justified by the principle of **justice**.

The principle of medical **confidentiality** is also already stated in the Hippocratic Oath. Because without seriously taken confidentiality, medical action is endangered in its core, since without it the necessary openness for the appropriate recognition of the disease and its determining conditions as well as an adequate understanding of the patient is almost impossible. This is particularly valid in a time in which the psychiatrist faces manifold demands for disclosure of data about his patient, by his team and other physicians, relatives, and students, as well as by health insurance companies or even agencies of research control. Confidentiality is especially important for people with mental illness in view of the widely existing and

stigmatizing skepticism they have to face and also due to the often specific vulnerability of their interpersonal relations.

Example
The candidate for the American vice presidency in 1972 lost his candidacy because the public was informed that he had been treated transiently in a psychiatric outpatient facility.

Ethical Rules

To sensitize psychiatrists for such ethical implications of their actions in order to protect the patients, a set of ethical rules, codices, etc. have been developed, both generally and specifically, for psychiatric practice as well as for psychiatric research, e.g., the following:

- Declaration of Madrid (1996) of the World Psychiatric Association (WPA) (1996) with its revisions, the latest one currently being formulated
- Opinions of the Ethics Committee on the Principles of Medical Ethics – With Annotations Especially Applicable to Psychiatry (2009) of the American Psychiatric Association (APA) (2009)
- Good Psychiatric Practice (2009) of the Royal College of Psychiatrists (RCP) (2009)

Specific guidelines for research with mentally ill people are, e.g., the following:

- Ethics of psychiatric research (2011), a position statement of the British Royal College of Psychiatrists (2011), related to:
- Guidelines for Researchers and for Research Ethics Committees on Psychiatric Research Involving Human Participants (2000) of the Royal College of Psychiatrists (2000)

Ethical guidelines especially for medical research are:

- The Declaration of Helsinki (1964) with its revisions up to 2008 of the World Medical Association (WMA) (2008).
- Chapter V, Articles 15–18 of the Convention on Human Rights and Biomedicine (1997) of the European Council (Europarat 1997).

  Psychiatrically relevant is §17.2 insofar as it declares research with ill persons who are not capable of giving informed consent as acceptable in specific exceptional cases. This has led to a highly controversial and emotional public debate in Germany (de Wachter 1997; Helmchen 1998, 2008, 2010; Maio 2010).
- European Textbook on Ethics in Research (2010) of the European Commission's Directorate-General for Research (European Commission's Directorate-General for Research 2010).

It should be noted that only laws and related governmental regulations are legally binding; declarations, recommendations, and other statements are not. Nevertheless the ethical norms of the latter, particularly those of the Declaration of Helsinki or of

national licensing authorities, have shaped the performance of clinical researchers as well as the acceptability of human research and its limitations and have influenced legislature.

Examples

The following contributions are only a very few examples of fairly different situations of psychiatric action that show the ethical complexity or even conflict-laden problems with which the psychiatrist is confronted. The examples are centered on specific aspects of respect for the autonomy of the patient and on the assessment of the risk-benefit relationship of each intervention – at present intensely discussed ethical questions.

The capacity of self-determination is psychiatrically relevant since mental illness may impair not only autonomy directly but also the social relationships of the person with a mental disease. This has now become much more relevant after the passage of the UN Convention on the Rights of Persons with Disabilities (CRPD) (2006), because the relationship of the capacity to consent to human rights is under discussion.

One aspect of self-determination is the informed consent as a binding requirement of each medical intervention. Not only sufficient information but also the patient's capacity to consent is required for its validity. Its assessment is important in order not to overload an incompetent patient with a responsibility that he cannot bear. However, its assessment is difficult and needs experience and accuracy, because the capacity to consent does not usually suddenly or completely disappear. Furthermore, it must be assessed with regard to a specific fact, and it depends on its complexity and meaning. Thus capacity to consent is to be assessed only gradually (in levels of strength) and in relation to the situation, but not generally as existent or not existent.

Szmukler and Ross describe the new development driven by service users towards respecting and enhancing self-determination of persons with mental illness both on the individual and on the institutional level. They recommend the use of advance statements, i.e., statements of what a service user wishes to be done and what not in case of a future episode of mental illness. They mention the controversies about the usefulness of such advance statements and discuss critically their limitations, e.g., the considerable uncertainty about circumstances under which such statements may be overridden – on which the contribution of Konrad and Müller goes into detail. Furthermore they point to the very new development of the participation of patients in some aspects of research such as setting the research agenda. Finally they argue for the abolition of a separate (risk-oriented) mental health legislation[2] in favor of a "fusion" legislation, based on impaired

[2]See also Callard et al. (2012).

decision-making capacity and best interests of the patient, irrespective of whether he or she has a mental or a somatic illness.

In contrast to this sign of a paradigmatical change towards the primacy of the patient's decision, Konrad and Müller discuss the existing legal situation and the uncertainties after the latest decision of the German Constitutional Court, which says that the existing law is insufficient with regard to clear criteria for compulsory treatment in case of compulsory admission. They also point to conflicts between ethical principles such as respecting the autonomy of the patient in case of refusal of a lifesaving treatment and the obligation of the physician as a guarantor; a series of rules has been established only if a person with full decisional capacity begins a hunger strike.

Another pertinent topic is addressed by the evaluation of the risk-benefit relationship of psychiatric interventions, i.e., the dimension of probability and thereby that of dealing with uncertainty and with aporias such as the impossibility to compare risks and benefits on the individual level with those on the societal level (Helmchen, chapter in this section). This is mainly valid for research projects. However, societal demands increasingly also influence the individual risk-benefit evaluation, mainly by economical and priority considerations.

These three examples may give only a glimpse of the breadth and complexity of ethical implications of psychiatry. Thus, the interested reader may find more examples in two books: Green and Bloch (2006) and Helmchen and Sartorius (2010).

Strengthening Self-Determination of Persons with Mental Illness

56

George Szmukler and Diana Rose

Contents

Abstract

"Self-determination" is taken to mean a freedom from forms of control or coercion deriving from external limitations imposed through common treatment practices and social institutions. The relationship between self-determination and discrimination is noted.

G. Szmukler (✉)
King's College London, Institute of Psychiatry, London, UK

J. Clausen, N. Levy (eds.), *Handbook of Neuroethics*,
DOI 10.1007/978-94-007-4707-4_55,

Four domains of mental health practice are considered in which patient self-determination can be enhanced. First, treatment at the individual level, how, in everyday practice, patient self-determination may be respected and enhanced in the relationships between the patient and members of the clinical team. The "recovery movement" and "advance statements" are examples. Second, how service user involvement may shape the services offered to patients at a local institutional level, a national level, and even an international level. Third is a recent development, the involvement of patients as collaborators in the conduct of research, as distinct from participating as research "subjects." Here there is the opportunity to influence the research agenda, including the questions that should be asked and thus what knowledge is deemed important in mental health care. Fourth, constraints that limit patient self-determination are examined. These include the range of "treatment pressures" exercised on patients reluctant to accept a proffered treatment, including those that can be termed "coercive." Powerful sociopolitical pressures, generated to a large degree by stereotypes of mental illness, act against patient self-determination. The way in which mental health law is constructed reflects these sociopolitical influences. Conventional mental health legislation discriminates against persons with "mental illness" and fails to respect their autonomy to the same degree as persons with "physical illness." Proposals for mental health law reform are discussed.

Introduction

A pragmatic approach will be taken to the meaning of *self-determination* in this chapter. The Oxford English Dictionary defines the term as "determination of one's mind or will by itself towards an object." There is clearly a relationship to the idea of *autonomy*. Without looking in detail at the meaning of this contentious concept, a distinction drawn by Bolton and Banner (2012) between two general spheres of application is helpful for our purposes. One "highlights the conditions under which a person's desires, beliefs, reasons and actions can be considered as originating in or belonging to the self, as authentic in this sense – as opposed to having some other origin." In contrast to this "personal" meaning is one that is "social" or "political," "in which context it means freedom of the individual citizen to carry on with his or her own affairs, in particular freedom of the individual from state control."

This distinction applies equally to *self-determination*. Common to both meanings of "self-determination" is a freedom from some form of control or coercion. In the "personal" sense, that control results in some way from limitations imposed by, for example, a mental illness; in the "social-political" sense it derives from external limitations imposed through the operations of social institutions. The latter will be the main focus. However, it is very likely that enhancing self-determination in the sociopolitical sphere (e.g., by listening to and respecting the person or by not excluding him or her from community participation, resources, and power) reduces the undermining of self-determination by the mental illness in the personal sphere.

A connection between self-determination in the sociopolitical sphere and "discrimination" should also be noted. To deny civil-political (sometimes called

"negative" rights) or socioeconomic ("positive" rights) to persons with mental illness on grounds that are clearly unfair is both discriminatory and an unwarranted interference with self-determination.

Outline of the Chapter

First we shall consider how patient or service user[1] self-determination may be enhanced rather than restricted in the way mental health care is practiced and its services organized. Treatment at the individual level shall be examined – how, in everyday practice, patient self-determination may be respected and enhanced in the relationships between the patient and members of the clinical team. Next, we shall examine how service user involvement may shape the services that are offered to patients at a local institutional level, up to a national level and even an international level.

Then a recent development that may come to shape mental health care at a fundamental level will be briefly described – the involvement of patients as collaborators in the conduct of research, as distinct from participating as research "subjects." Here there is the opportunity to influence the research agenda, including the questions that should be asked and thus what knowledge is deemed most important in mental health care.

Finally, constraints that limit patient self-determination shall be examined. These include the range of "treatment pressures" that may be exercised on patients who are reluctant to accept a proffered treatment, including measures that can be termed "coercive." Powerful sociopolitical pressures, generated to a large degree by stereotypes of mental illness, act against patient self-determination. The way in which mental health law is constructed reflects these sociopolitical influences. We shall examine how conventional mental health legislation discriminates against persons with "mental illness" and fails to respect their autonomy to the same degree as persons with "physical illness." Proposals for mental health law reform aimed at dealing with such discrimination will be discussed.

Thus self-determination will be discussed under four headings:

1. Treatment at the individual level
2. Treatment at the level of service design or function
3. Research in mental health: involvement in research; setting the research agenda
4. Treatment pressures, coercion, and the law relating to mental health

[1]A point of terminology should be noted here. There are various terms that have been used to describe those who use mental health services, for example, "patients," "consumers," "clients," "survivors," and "service users." These terms may differ in the sets of values they imply. We shall use the terms "service user" and "patient" interchangeably, as they may be, at the present time at least, the least controversial and ones with which the coauthors of this chapter are reasonably content.

Treatment at the Individual Level

The treatment wishes and preferences of patients with mental illness, especially those treated in public mental health services, have not achieved a level of regard comparable to those of patients in other medical specialties. It is worth noting, for instance, that the history of *voluntary* inpatient treatment in a public mental hospital is relatively recent. Jurisdictions began to introduce "voluntary" status in the early twentieth century. For example, in the Netherlands this became possible in 1904; in Victoria, Australia, in 1916; in England not until the passing of the Medical Treatment Act in 1930 (although there were ways of achieving it earlier); and in Italy, not until the passing a special decree in 1968.

Some approaches, mainly recent, to enhancing patient self-determination will now be considered.

The "Recovery Movement"

The past two decades have seen a significant change in accounts of the philosophy of care, most evident in the Anglophone countries. Whether a change will be largely at the level of rhetoric or whether it signals a real change in how the patient's voice is heard remains to be seen. The change in approach is known as the *recovery movement*. The precise meaning of "recovery" in this context varies from one authority in the field to another; but central to the notion is an enhancement of patient self-determination and the view that the goals of treatment are to be largely set by the patient, not the clinician (Slade 2009). Conventionally in medicine, "recovery" means restitution to the pre-illness state, with the loss of symptoms and dysfunctions. "Recovery" in the "recovery movement" sense has a different meaning. An influential paper by Anthony (1993) gives an often-quoted definition:

> a person with mental illness can recover even though the illness is not 'cured'. Recovery is a way of living a satisfying, hopeful, and contributing life even with the limitations caused by illness. Recovery involves the development of new meaning and purpose in one's life as one grows beyond the catastrophic effects of mental illness.

"Recovery" (or "personal recovery") in this sense comprises both a "journey" (or "being in recovery") as well as an "outcome," but an outcome that does not necessarily require symptom loss. A key goal is to find a new way of living, through self-agency. It involves regaining a sense of self, becoming empowered to take control of one's life, and combining optimism for a better future with an acceptance of the past.

This change in philosophy requires a change in some of the traditional values underlying mental health care. Slade and Davidson (2011) describe it thus:

> Previous preoccupations (e.g. risk, symptoms, hospitalisations) become seen as a subset or special case of the new paradigm. By contrast, what was previously of peripheral interest (i.e. the patient's perspective) becomes central. This involves a reversal of some traditional clinical assumptions. Mental illness is a part of the person, rather than the person being

> a mental patient. Having valued social roles improves symptoms and reduces hospitalisation, rather than treatment being needed before the person is ready to take on responsibilities and life roles. The recovery goals come from the patient and the support to meet these goals comes from the clinician among others, rather than treatment goals being developed which require compliance from the patient. Assessment focuses more on the strengths, preferences and skills of the person than on what they cannot do.

Slade and Davidson suggest there are four ways in which clinicians can support an individual's recovery: fostering relationships, promoting well-being, offering evidence-based treatments to achieve the patient's recovery goals, and tackling social exclusion and stigma. They argue that mental health services need to be oriented around these recovery support tasks if they are to support recovery. Other writers have emphasized the importance of a reawakening of hope, of peer support and narratives of recovery, of a "social model" of disability, and of the need for risk taking (e.g., Repper and Perkins 2003; Kelly and Gamble 2005).

Although the "recovery" concept has now found a place in government mental health policy in the USA, UK, Australia, and New Zealand, doubts have been expressed concerning its full implementation. Changes in practice are always difficult to achieve, and those involving substantial shifts in underlying values, especially so. Concepts like "recovery" that have their origins in the service user movement can lose their vitality when "standardized" for institutional settings. Bonney and Stickley (2008) following a detailed review of the literature see some major limitations:

> With such a current focus upon risk in Western society, it is virtually inconceivable that statutory health care providers will ever fully embrace the recovery paradigm that involves self-management and has choice, hope, freedom and autonomy at its core. Furthermore, these values are extremely difficult to measure in a system that revolves around targets and outcomes. While there may be workers within the system who genuinely subscribe to recovery principles, they will struggle to practise according to those values in a system that pays only lip-service to a philosophy that is very dependent upon human values and beliefs.

Some patients might opt for seeking recovery entirely outside conventional mental health services. The availability of such facilities is highly problematic, because of funding as well as the constraints identified above. A possible unintended consequence of the "recovery" idea is that if "recovery" places a high value on self-management and if a good outcome for the patient can be achieved without cure, there may be a temptation, especially when finances are tight, to cut back on some services. Some patients have expressed concerns about a new set of normative demands that they fear they may be unable to meet and that failure to embark on what is seen as a "recovery journey" might leave them unsupported by both peers and services.

Despite these limitations there is an important value in the "recovery" approach. In some ways, the "recovery movement" positions patients with a mental illness in the same place as the generality of medical patients. It offers the same scope for choosing (or rejecting) treatment in accordance with their values and preferences. What appears to be a radical change in treatment philosophy is in many respects the removal of long-standing discrimination in mental health care if a patient's goals

should be at variance with those of the clinician. However, use of the word "recovery" may be less than optimal. It creates confusion in the minds of mental health professionals who invariably argue that recovery (albeit in the medical sense) has always been their aim; to suggest otherwise may appear to be an unfounded criticism and lead to resistance. Perhaps a term such as "reinstatement" or "re-engagement" might have been better.

Advance Statements

A specific clinical tool aimed at enhancing self-determination is the "advance statement" (AS). An AS allows a patient, when well, to state treatment preferences in anticipation of a time in the future when, as a result of the effects of illness, he or she may not be capable of making or expressing treatment decisions. The anticipated loss of decision-making capacity usually occurs during a relapse of a psychosis. An important aim of an AS is to give patients greater say over their treatment at a time of crisis and thus to reduce the need for "coercive" interventions.

A typology of ASs has been described by Henderson et al. (2008a). They vary along the following dimensions: whether patient or service provider led, whether legally binding or not, and whether facilitated by a person independent of the clinical team. At least three major types of AS have been described: "crisis cards" (CCs), "joint crisis plans" (JCPs), and "psychiatric advance directives" (PADs).

In a **crisis card** (CC) patients state their treatment wishes or nominate a person familiar with their preferences, without involvement of their treatment team. It has its origins in the service user self-advocacy movement and is entirely patient led. In some jurisdictions, for example, under the Mental Capacity Act 2005 (MCA) in England and Wales, stated treatment refusals now have legal force but can be overridden by mental health legislation. CC uptake has been very limited.

In contrast to CCs, the **joint crisis plan** (JCP) is the product of a semi-structured discussion between patient (supported by a relative, friend, or advocate) and the clinical team. The JCP reflects an agreement on what measures should be taken if a relapse should occur. A facilitator, independent of the clinical team, ensures that the patient's voice is given prominence (Sutherby et al. 1999; Henderson et al. 2004). A JCP is not legally binding (although as noted above specific treatment refusals may have legal force in some jurisdictions). However, the clinical team makes it explicit that while it will attempt to honor the terms of the JCP, compliance with all aspects cannot be guaranteed. While the JCP is provider initiated, it achieves an agreement in which the patient's voice is key, and is formulated in the patient's words. The JCP's specificity of content, based on a detailed reconstruction of past illness episodes and the treatment offered, is an important advantage since relapse tends to take a more or less stereotyped form.

A randomized controlled trial of JCPs has been conducted in South East England (Henderson et al. 2004). Almost 40 % of patients who were eligible took up the

opportunity to complete a JCP. Eligible patients were those with a diagnosis of a psychotic illness or bipolar disorder and who had had at least one admission in the previous 2 years. Compulsory admissions over a 15-month period were halved compared to a control group. On follow-up patients said their agreements were given freely and without pressure and that they felt more in control of their mental health problems as a result of making a JCP (Henderson et al. 2009). We await the results of a large replication study that is soon to be completed.

Psychiatric advance directives (PAD) may take three forms: (i) specified treatments that are refused or requested; (ii) statements about values, attitudes, or preferences to guide those making treatment decisions for the patient; and (iii) nomination of a person to act a “substitute” (or “proxy”) decision-maker. A PAD assumes the patient had decision-making capacity when it was made and that the circumstances in which the PAD is triggered are those that were anticipated.

PAD legislation now enacted in a number of states in the USA ostensibly makes such directives legally binding. Nevertheless, there is considerable uncertainty about circumstances when PADs may be overridden (Swanson et al. 2006a). Civil commitment legislation may do so if it specifically authorizes involuntary treatment. However, in those states where a separate step requiring the patient’s consent before treatment can be given following detention in hospital (the detention being based, e.g., on a separate dangerousness standard), a PAD may prevail. Some PAD statutes, for example, in Pennsylvania, stipulate that the patient’s wishes may be overridden if they violate “generally accepted community practice standards.” How this should be interpreted is not clear. It is noteworthy that the evidence on PADs to date shows that refusal of all treatment alternatives is rare (Swanson et al. 2006b). A controversial issue is whether a PAD making a treatment refusal very likely to lead to a life-threatening risk should be respected or not. This is too big a subject to be considered here.

A **facilitated PAD** (F-PAD) was introduced following surveys showing that despite an apparently widespread appeal of PADs, few patients actually make one, probably because of their complexity. In an F-PAD a trained facilitator explains what a PAD involves and, if the patient chooses to opt for one, assists with its completion (Swanson et al. 2006b). Sometimes the service provider is brought into the process. A randomized controlled study of F-PADs found that facilitation resulted in a highly significant increase in the number of patients who decided to make a PAD (61 % vs. 3 % of controls). At 1-month follow-up, those with an F-PAD reported a better therapeutic alliance with their clinicians and were more likely to say that they received the services they needed (Swanson et al. 2006b). A later report from this study found that the number of “coercive interventions” (e.g., police involvement, involuntary treatment, seclusion) over the succeeding 2 years for those who made a PAD was considerably fewer compared to patients who chose not to make a PAD (Swanson et al. 2008).

Thus there is evidence that some forms of AS can reduce coercive interventions and improve outcomes from the patient’s perspective. Patients sense of self-determination may be enhanced; from a practical point of view, the information

contained in an AS may ensure that the most appropriate treatment is given when information from other sources is unavailable. JCPs suggest that patients can effectively voice their treatment wishes outside a legal framework.

Hospitalization

Admission to a psychiatric hospital is usually an especially distressing experience, exacerbated by coercive treatment interventions. However, there is evidence from a number of non-controlled studies that the use of seclusion or of physical restraint can be significantly reduced (Gaskin et al. 2007); Hallerstein et al. (2007). Approaches have been varied, are multiple, and have usually involved system changes – for example, state policy and regulation changes aimed at reducing seclusion, monitoring and analyzing episodes, strengthening leadership; staff education, changing the ward environment, increasing staff to patient ratios, creating special emergency response teams, and treating patients as active participants in interventions to reduce seclusion. A study attempting to increase the involvement of inpatients in planning their treatment did not affect the "perceived coercion" experienced by the patients (Sorgaard 2004). More research in this area is clearly warranted.

Treatment at the Level of Service Design or Function

Here developments in the UK will serve as an example, but it should be noted that the extent of service user involvement varies hugely, even within and between countries with well-developed mental health policies and services. New legislation in 1990 (Community Care Act) (Department of Health and Social Security 1990) ushered in the policy of recipients of health and social care services being consulted about the way in which these services should be configured and delivered locally. Since then, and incrementally, successive governments have pursued service user involvement in service design and function (Department of Health 2000, 2011). The most recent is the UK government's 2011 policy statement "No Health Without Mental Health" which reiterates that patient choice should be at the heart of care and promises "no decision about me without me." It should perhaps be noted that this is a reprise on a long-standing slogan of the disability movement "nothing about me without me."

Patients often serve on committees charged with developing or reconfiguring services and may also sit on appointment panels for some categories of staff. A major mechanism through which the government now seeks to increase choice over care is through the introduction of personal budgets (PBs). Instead of funding services through blocks of money to health-care providers, service users are to be given a PB to buy care that suits their needs. This, it is said, will ameliorate ghettoization and dependency (features of traditional day services for example) and enhance service user autonomy.

A further mechanism for service users to influence local policy is to allocate reserved places on the governing boards of hospital and community health-care organizations. In this way, service users have a voice in local decision-making and contribute to the policies and strategy of the facility from which they receive services. Some user "governors" conceive of themselves as "representing" their constituency, but others act as individuals with no mandate.

A question arises as to whether there has, in the decades since 1990, been a significant transition in the ways in which service users can affect service configuration and delivery. The traditional method was through *collective* organization where groups of service users, often user led, consulted or campaigned to bring about change. They were often criticized by service providers as "unrepresentative" (Rose et al. 2010). With the shift to PBs and the development of user governor structures, it may be argued we are seeing something much more individualized. This befits an ideology of the moment, but it may have shortcomings in practice. In a climate of financial austerity, for example, only a select few have access to PBs and many have no services at all. The arguments about the parlous nature of ghettoization and dependency may mean, in effect, that many rely on inappropriate or underfunded provision. The ethical requirement for self-determination in such circumstances may ring hollow and amount to little more than an obligation to be a free and liberal subject.

Partners in Research

"Service user (or patient) involvement in research" refers to the active involvement of service users as partners or collaborators in the conduct of research – helping to design, deliver, and disseminate research. It is distinct from service user participation as research "subjects." Service user involvement in research is a recent development, starting in the mid-1990s. In the UK it is now supported by a number of Department of Health policies and is becoming increasingly developed through its Clinical Research Networks, set up to provide logistic support for high-quality medical research (http://www.nihr.ac.uk/infrastructure/Pages/infrastructure_clinical_research_networks.aspx).

Demonstrating evidence for an impact of service users on research is complex and still in its infancy. Involvement may occur at different stages of the research enterprise and with different expectations – for example, improving the practical aspects of the study to enhance recruitment (Donovan et al. 2002), choosing meaningful outcome measures (Crawford et al. 2011), and improving the quality of data acquisition or interpretation (Gillard et al. 2010; Rose et al. 2011). These require different methods of evaluation. While evaluation has not generally reached this level of sophistication, evidence of impact is accumulating. For example, Vale et al. (2012), surveying service user involvement in studies run by the Medical Research Council Trials Unit, found that researchers reported a range of positive impacts on the research and researchers, including

improved credibility, design and quality, trial recruitment, and dissemination. Other evidence, mainly from case studies, is consistent with this report (Staley 2009).

But besides the issue of quality of research, there is also a strong moral case. The framework is well articulated in Kitcher's (2001) notion of a *well-ordered science*. It revolves around how a research agenda should be set? While traditionally this has been decided by "elites" – communities of scientists, perhaps in association with a privileged group of outsiders, such as the funders of research or industry – Kitcher argues this is not an acceptable basis for setting a research agenda. Science is clearly embedded in society, and since it potentially affects the lives of all, a range of voices needs to be heard. However, what he terms "vulgar democracy," baldly following the wishes of the general public, is not the answer; it leads to an emphasis on current "hot topics," usually with a short-term focus. The basis for a *well-ordered science* favored by Kitcher is "enlightened democracy," founded on "tutored preferences." Representative citizens in dialogue with scientists would examine a particular problem, what is known about it, how it might be researched, and the problems and prospects for knowing more. They will thus understand the goals, methods, and limitations of a particular research approach for solving a particular problem. They become deliberators with "tutored preferences" who can engage in discussions with the scientists, funders, government, and each other about research priorities for the common good.

This "tutoring" process is dialogical; the scientists will learn from the relevant nonscientists about the personal meanings and sociopolitical implications of their knowledge. Ideally then, the research agenda will be set by informed deliberators who will determine the problems to be researched, the kinds of science best suited to solve them, and the constraints (e.g., ethical, financial) that need to be imposed. In medical research, service users are a key stakeholder group.

A well-ordered science along these lines is obviously an ideal. However, service user involvement in the conduct of research has generated practices that can move us in that direction. Certainly, there are obstacles in understanding each other's viewpoints. For lay persons the science can be difficult to understand, as can be the complex workings of academia, while for the researcher, the experience of mental illness can be difficult to appreciate. Progress towards a "well-ordered science" in mental health may be especially challenging; for instance, so much is contested, even the term "illness" itself and thus of the value of the application of a range of scientific approaches to mental health "problems."

Nonetheless, through an organization such as the UK Mental Health Research Network, one has seen the research agenda being increasingly influenced by patients (Staley 2012; Staley et al. 2012). All studies adopted for support have their involvement, and it is apparent that service users are increasingly engaged in decisions concerning the aims, methods, and design of studies. Serving as members of project management or steering committees is now common. We anticipate that over time, service users will have an increasing influence in setting the research agenda and perhaps in creating new kinds of knowledge.

Coercion and the Law Relating to Mental Health Care

In this section constraints on patient self-determination will be examined that arise from the actions of mental health professionals, the construction of the mental health service "system," and measures sanctioned by mental health law.

Coercion

One can think in terms of a hierarchy of *treatment pressures* placed on reluctant patients: "persuasion," "interpersonal leverage," "inducements" (or offers), threats, compulsion (Szmukler and Appelbaum 2008). Persuasion, an appeal to reason, and "interpersonal leverage," appearing to be disappointed by the patient's refusal in the context of a valued relationship, are not especially problematic, though one should be aware of the subtle influence of the latter. Needing closer attention are the last three. It can be argued that *coercion* in a technical sense enters at the point of "threats." In contrast to an inducement, a threat is a conditional proposition that if not accepted by the patient makes the person, in an important sense, usually according to an accepted set of values, worse off. "If you do not take your medication, then you will be admitted to hospital involuntarily" is a threat. Rejecting the proposition leads to one being worse off than one was in the "baseline" position, prior to the proposition having been made – being deprived of one's liberty. An offer, on the other hand, if not accepted does not make the person worse off. "If you take your medication, you can join a patient group on a day trip to a lovely seaside town"; rejection of the proposition leaves the person's baseline position unchanged; it is the same as if the proposition were never made.

It is worth noting that leverage (threats) of various kinds, short of compulsion, are common in psychiatric practice – a study of community patients in Oxford, for example, found that up to 30 % of patients had experienced these in the past (Burns et al. 2011).

While inducements are not on this account coercive, they may still be problematic. An example is paying patients with a psychosis to take medication (Priebe et al. 2010). Most clinicians have a moral intuition that this is in some way problematic. Factors that may contribute to this feeling are exploitation (the clinician in some way takes unfair advantage of the patient), unfairness (why should the unwilling patient be paid, but not the prudent one), and an exchange that involves very different domains of value that cannot be measured on the same metric (e.g., selling a child). The higher value – respect for the person, something that mental health services should be enhancing not diminishing – is somehow degraded (Szmukler 2009).

Moving up the hierarchy to "compulsion," there is a striking observation to be made. This is the extraordinary variation in its use between countries – and within countries. There was thirtyfold variation in involuntary admissions to hospital

across a group of European countries in 1998–2000 (Salize and Dressing 2004). Within countries, large variations have also been noted, for example, fivefold in Norway, despite the same legislation and same service structures. Just as significant are changes in rates of involuntary hospitalization over time. In England and Wales, compulsory admissions to hospital increased by 63 % between 1984 and 1996 (Hotopf et al. 2000). Numbers in Sweden declined over the same period (Kjellin et al. 2008). Large variations in rates of application of coercive measures following admission are also evident, for example, in the use of seclusion and physical restraint. In a 10-country study, this varied between 21 % and 59 % in first 4 weeks of involuntary admissions. Rates also vary for different ethnic groups in a country.

Politics, culture, and local "custom and convention" are highly influential. A positive inference that might be drawn from an otherwise troubling set of findings is that in many places there may exist scope for significant reductions in countries with high rates.

Recent studies have also shown that patients subject to involuntary admission often fail, in retrospect, to endorse the action. A recent study in England found this to be the view of 60 % of patients followed up 1 year later (Priebe et al. 2009).

While coercion and some types of offer may constitute, on the face of it, a wrong, it does not mean that it cannot be justified in some circumstances – appropriate criteria for involuntary treatment, for example, define those. One approach, for example, is based on a "capacity-best interests" test. We return to the subject below.

Discrimination and Mental Health Law

There is a strong argument (Dawson and Szmukler 2006; Szmukler et al. 2010) that mental health legislation of the conventional kind discriminates unfairly against persons with mental illness and undermines rights to self-determination (or "autonomy") that, by contrast, are un-controversially possessed by patients with "physical disorders." Unlike the situation in all other medical specialties, such mental health law allows persons with mental illness to be treated against their will even if they retain decision-making capacity (or capability) – that is, they are able to understand and retain the information relevant to their illness and the treatment (e.g., the likely consequences of having or not having the treatment), to appreciate its relevance to their predicament, and to be able to reason with it in the light of their values and life choices, thus deciding whether to undergo the treatment or not.

The necessary criteria in most jurisdictions for treating a patient without their consent in general medicine is that the patient lacks such capacity and that the treatment is in some sense in the person's "best interests." The latter criterion is variously understood, but the strongest case can be made for "best interests" referring to what the patient would have chosen in this predicament if they had capacity – based perhaps on an advance statement (such as a JCP) or on

a consideration by those who know the patient well of his or her values and life choices that would be relevant. The usual criteria for persons with mental illness, on the other hand, are based on (i) the presence of a "mental disorder" and (ii) the presence of a "risk" of some kind to the person's health or safety or to the safety of others. These risk-based justifications, it is suggested, reflect deeply entrenched stereotypes of people with a mental illness – that they are intrinsically less than competent persons because of their illness or that they are dangerous.

In order to deal with this discrimination, Dawson and Szmukler (2006) have proposed a major reform of existing mental health legislation. Indeed, they argue for the abolition of separate mental health legislation altogether, in favor of a single, comprehensive statute with a single set of criteria governing involuntary treatment of all persons, no matter what the health setting – general medicine, surgery, or mental health. The proposal is based squarely on an impairment of decision-making capability as the essential gateway to a consideration of involuntary treatment, followed by a "best interests" assessment. The same legislation could also readily cover social care where an action such as a nursing home placement is being considered that is contrary to the person's wishes. The law that is being proposed is termed a *fusion law* as it combines, on the one hand, the respect for patient autonomy that one finds in general medical law or "capacity" legislation based on impaired decision-making capability and, on the other hand, the regulation of detention and forced treatment, once instigated, that is well covered by civil commitment law, for example, by specifying how it is to be authorized, by whom, for how long, where, how appeals are to be made, and how often. Capacity legislation (as in the Mental Capacity Act 2005 in England) usually fails to do this adequately.

Involuntary treatment in the community has been a highly controversial recent development in mental health care. The *fusion law* approach would be compatible with involuntary community treatment provided the patient lacked capacity and the treatment was in their best interests. Another important difference compared to current risk-based legislation is that it would necessarily cease once capacity was recovered.

A capacity-best interests approach may also provide a framework for considering the justification for "coercive" interventions short of involuntary treatment (Szmukler and Appelbaum 2008).

UN Convention on the Rights of Persons with Disabilities (CRPD)

This convention, signed by 153 states and ratified by 119 as of August 2012 (United Nations 2006), may have a far-reaching effect on involuntary treatment. Though *disability* is not defined, at least some forms of mental illness, especially those that are serious and long term, are taken by the Committee on the Rights of Persons with Disabilities as comprising a disability. The CRPD adopts a social model of disability, where a disability has as much to do with the social responses and accommodations to a person with an impairment, as the impairment itself.

Notably, and controversially, the CRPD omits any mention of "substitute decision-making." The model is one of *supported decision-making* – the assumption is that people with disabilities can articulate an authentic preference if adequately supported to do so. Article 12 states that people with disabilities have "legal capacity on an equal basis with others." Not only do they hold rights, but they, like everyone else, have the right to exercise or act on those rights. The right to liberty (Article 14) states: "the existence of a disability shall in no case justify a deprivation of liberty." The UN High Commissioner for Human Rights (2009) has interpreted the intention as follows: "[48.]. . . unlawful detention encompasses situations where the deprivation of liberty is grounded in the combination between a mental or intellectual disability and other elements such as dangerousness, or care and treatment. Since such measures are partly justified by the person's disability, they are to be considered discriminatory and in violation of the prohibition of deprivation of liberty on the grounds of disability. . ." That is, if the disability comprises an arm of a set of criteria for involuntary treatment, it is discriminatory. "The legal grounds upon which restriction of liberty is determined must be de-linked from the disability and neutrally defined so as to apply to all persons on an equal basis." On this interpretation, States must repeal such laws; but such laws, as noted in the previous section, are almost the norm.

It has been argued that involuntary treatment and substitute decision-making are incompatible with the CRPD (Bartlett 2012; Minkowitz 2011). Some recent observations by the Committee on the Rights of Persons with Disabilities indicate that mental health law and discrimination will be the subject of special scrutiny. (See, e.g., Committee on the Rights of Persons with Disabilities. Sixth Session 19–23 Sept 2011. Concluding observations).

It can be argued that an involuntary treatment law that is decision-making capability and best interests-based, and applies to both physical and mental illness, such as the "fusion law," would be "disability neutral." Such law applies equally to the well person who, for example, suffers a head injury in an accident and to the person with schizophrenia who experiences a relapse of their illness. However, the "fusion law" approach may need to be reframed in order to emphasize supported decision-making and to recast the concepts of "decision-making capability" and "best interests" in terms of respect for, and facilitation of, the person's "will and preferences" (Szmukler et al. 2014). We wait to see how the CRPD will be interpreted, but it is likely to significantly change the discourse around involuntary treatment.

Although this section has focused on limitations on patient self-determination as a result of involuntary treatment, further limitations arise from failures to ensure equal socioeconomic rights for persons with mental illness. These are addressed in the CRPD and include, for example, the right to home and family life (Art. 23), the right to education (Art. 24), and rights to health (Art. 25) and habilitation and rehabilitation (Art. 2). Some of these rights have been reframed so as to have particular relevance to people with disabilities: the right to nondiscrimination (Art. 5), the right to independent living and community

inclusion (Art. 19), the right to personal mobility (Art. 20), the right to work and employment (Art. 27), the right to participation in cultural life (Art. 30), and the right to be free from exploitation and abuse (Art. 16).

What has been presented here is obviously a Western, high-income country, perspective on mental health legislation. However, it should be noted that around 25 % of the world's population live in states that have no mental health legislation and that in many states that do have such legislation, it is in any case not fully implemented.

Conclusions

Four domains have been considered where developments over the past decade or so seem to promise an enhancement of self-determination for persons with a mental illness – clinical practice, service design, the conduct of research, and mental health law. That these changes have occurred across a broad front suggests that there has been a change in attitudes and policies at a fairly deep level, and is encouraging. However, in each of the domains, our discussion has indicated that obstacles remain and that rhetoric may outstrip practice. It would be foolish to think that such long history of profound discrimination and stigmatization can be easily undone.

Compulsory Interventions in Mentally Ill Persons at Risk of Becoming Violent

57

Norbert Konrad and Sabine Müller

Contents

Abstract

Medical treatments are allowed only with the informed consent of the patient. The German civil commitment laws contain articles, which allow the commitment of mentally ill persons, who are acutely dangerous for themselves and/or for important legal rights of third persons. However, neither a mental illness alone, nor missing insight into the illness and the need for treatment are sufficient for compulsory admission. The most controversial issue is whether persons who are unable to consent have a right to live with their illness, particularly their mental

illness, or rather a right for an effective treatment of the illness (implicitly acknowledging the subjective torment and, at times, sheer terror the symptoms cause for the psychotic individual). In Germany, compulsory treatments of patients under custodianship and in confinement can be allowed by courts if certain conditions are fulfilled: The patient is not able to consent to the necessary treatment; the physicians have tried to convince him; the treatment is necessary to avert considerable health detriments; the compulsory treatment is used as a last resort treatment, and its benefit-risk balance is positive. A rather new instrument for avoiding compulsive measures in states of dangerousness is the mental health advance directive. Preliminary results are promising: Patients who have written advance treatment directives committed less violent acts, needed less use of social workers time, showed greater improvement in their working relationship with their clinicians, and were more likely to report satisfaction with their treatment.

Legal and Ethical Issues of Compulsory Interventions in Mentally Ill Persons

Generally, medical treatments are allowed only with the informed consent of the patient. Therefore, it is both ethically and legally unacceptable to treat a legally competent patient without his consent or even against his declared will. The right for autonomous decision making includes the right to die and therefore the right to refuse life-saving treatments. This conception has become predominant in medical ethics during the last decades; by now, it has entered the legislations of many countries. Particularly in Germany, the civil law (BGB § 1901a) clearly states that a legally competent adult can rule out certain life-saving treatments by declaring his will in an advance directive. The will of a mentally ill individual has to be respected, too, even if the patient refuses medically necessary treatments – provided that he or she is able to consent. Consent to treatment should be sought from all patients, including offenders suffering from a mental disorder, provided that they have the capacity to consent. If patients lack this capacity, physicians should seek their assent, even if the consent of the custodian would be legally sufficient, i.e., they should inform the patients about the intended treatment in adequate wording, so that the patients can understand the information – and ask them whether they assent to the treatment (Sammons 2009). Obtaining the patient's consent is essential to build up a "therapeutic alliance," which increases the likelihood of committing the patient to the treatment offered. This does not mean that psychiatrists should try to persuade patients to accept the proposed treatment; rather, it means that psychiatrists should try to convince patients with truthful information about the proposed treatment even though the patient might have refused it initially, be it because of fear, disinformation, or psychotic ideas. Each ethically acceptable effort should be made to convince the patient to cooperate. The use of coercion, allowing for "choosing" between the two evils of physical restraint and medication, should be avoided.

Nevertheless, a few patients will remain who will not consent to the proposed treatment and whose suffering will foreseeably increase or who will even die

without treatment. In these cases, physicians are confronted with the ethical dilemma whether the patients' right to decide autonomously prevails over their right for physical and mental health and for life. Although the predominant ethical and legal systems favor autonomy over the right to live, for many physicians, this dilemma will remain hardly endurable.

The situation is even more complicated for persons who are unable to consent – be it because of acute mental disorder (e.g., psychosis, suicidal ideation), mental disability, severe dementia, or coma. Nevertheless, also for these patients, decisions about any medical treatments have to be made according to their will: firstly, according to their formerly declared will (ideally in an advance directive), secondly, to their assumed will, and thirdly (in case that the latter two are unknown), in their best interest.

The most controversial issue is whether persons have a right to live with their illness, particularly their mental illness, or rather a right for an effective treatment of the illness (implicitly acknowledging the subjective torment and, at times, sheer terror the symptoms cause for the psychotic individual). The Federal Constitutional Court of Germany has supported the concept of the "freedom for illness," which means the right to refuse certain or all medical treatment and is part of the constitutional rights of patients for autonomous decision making. In a literal understanding, this right could imply that the society has to leave persons suffering from their illness if they refuse any treatment. This interpretation is favored as well by neoliberal opinion leaders as by anti-psychiatrist groups. Nevertheless, this interpretation is too narrow: As the medical ethicists Beauchamp and Childress have argued, the obligations to respect autonomy do not apply to persons who show a substantial lack of autonomy, because they are immature, incapacitated, ignorant, coerced, or exploited, for example, infants, irrationally suicidal individuals, severely demented subjects, or drug-dependent patients (Beauchamp and Childress 2013, p. 108). This position has also recently been supported by the Federal Constitutional Court of Germany (in accordance with the Convention on the Rights of Persons with Disabilities) in a decision about forced treatment of a forensic patient: The freedom for illness must not be considered detached from the real capacities of free decision making which may be limited by illness. Therefore, the state is not obligated to leave forensic patients to the fate of permanent confinement because of the primacy of an illness-determined will, but coercion has to follow a rule of law (Bundesverfassungsgericht, 2 BvR 882/09, 52, 23.03.2011). Therefore, the state parliaments are urged to reformulate their civil commitment laws so that compulsory treatments will be made possible under strict legal conditions.

Nevertheless, the aforementioned decision has an immense influence on jurisdiction about involuntary treatment and has strengthened the position that the patient's autonomy dominates over the patient's right for mental health or for life, and overrules his best interest as seen by independent custodians or medical professionals. Particularly, the Federal Constitutional Court has judged that coerced treatment against the will of the forensic patient is not allowed to protect other persons against criminal acts which the patient might commit after discharge. The Court argues that future crimes could be prevented by detaining the patient in a psychiatric institution without treatment.

Following the aforementioned decision of the Federal Constitutional Court of Germany, several local courts and district courts have applied this decision to lawsuits about the issue of compulsory treatment of mentally ill patients under legal custodianship. They decided that the German civil law does not allow compulsory treatment. This interpretation was supported by the Federal Supreme Court (Bundesgerichtshof, 20.06.2012, XII ZB 99/12) which gave up its former position in order to follow the decision of the Federal Constitutional Court of Germany. Within only 7 months, the relevant articles of the German civil law have been modified. Since January 2013, compulsory treatments of patients under custodianship and in confinement can be allowed by courts if certain conditions are fulfilled: The patient is not able to consent to the necessary treatment; the physicians have tried to convince him; the treatment is necessary to avert considerable health detriments; the compulsory treatment is used as a last resort treatment and its benefit-risk-balance is positive. This law can also be applied to forensic patients under custodianship.

Although the legality of commitment and of compulsory treatment depends completely on the label "capacity to consent," there is no standardized and validated tool to assess this capacity. Indeed, there are at least three instruments trying to measure the ability for informed consent, namely, the Mac Arthur Competence Assessment Tool-Treatment (Mac CAT-T) (Grisso and Appelbaum 1998), the Hopkins Competence Assessment Test (HCAT) (Janofsky et al. 1992), and the assessment tool of the AGFP (Nedopil et al. 1999). These instruments try to quantify a patient's ability to understand, appreciate, reason about, and express a therapy choice. It has been rightly criticized that the Mac CAT-T is merely orientated on the rational understanding, but neglects emotional and value-based prerequisites of decisions which are often affected by psychiatric disorders (Vollmann 2008), a shortcoming, which the AGFP instrument tries to avoid. Furthermore, it has been criticized that the neurological prerequisites of autonomous decision making are neglected even in the medical ethical debate about autonomy (Müller and Walter 2010). In medical practice, the capacity to consent is evaluated often rather informally or based on the personal psychiatric experience. Surprisingly, the Federal Constitutional Court has not criticized this shortcoming (Müller et al. 2012a), seemingly based on its general assumption that professionals are free in the choice of medical methods if they adhere to the current state of the art.

In Germany, compulsory treatments are legal in situations of imminent danger for self or others, if certain conditions are fulfilled.

Legal and Organizational Frame for Mentally Ill Offenders

Compulsory Admission

In Germany, mentally disordered offenders are subject to special legal regulations (Konrad 2001), which are based on the concept of criminal responsibility: Offenders who are not criminally responsible and not considered dangerous are hospitalized, if at all, in general clinical psychiatric institutions. If serious

offenses are expected from offenders who are considered to have at least diminished criminal responsibility, they are admitted, regardless of therapeutic prospects, to special forensic psychiatric hospitals (Art. 63 German Penal Code) under the authority of the state ministries of health. The number of detainees housed there was 6,750 as of March 31, 2012 (www.destatis.de). Offenders dependent on psychoactive substances with sufficiently good therapeutic prospects, independent of their assessment of responsibility, are admitted to special forensic drug treatment facilities, which are also under the authority of the ministry of health (Art. 64 German Penal Code). As of March 31, 2012, the number of detainees housed there was 3,526 (www.destatis.de). All other mentally disordered offenders, including individuals with schizophrenia who are considered criminally responsible despite their illness, may be sentenced to prison, if no milder sanctions like a fine are ordered by the court. In many cases, it may depend on coincidental constellations whether a mentally ill offender is committed to a forensic psychiatric or penal institution (Marneros et al. 2002).

Prisoners who pose a danger to themselves, for example, after a suicide attempt or other self-destructive behavior, are frequently admitted to psychiatric wards within the prison. There are, however, no legal regulations about the admission, treatment, and dismissal of those patients. The penal detention code and the federal and state laws neither stipulate nor prohibit psychiatric prison wards.

Compulsory Treatment and Force-Feeding in Prisons

If mentally disordered prisoners are under legal custodianship, the custodian can request a medically indicated compulsory treatment from the court according to the new civil law. For all other mentally disordered prisoners, compulsory treatment is regulated by the penal law, the pertinent provisions of which correspond to the standards for compulsory treatment within the framework of state commitment laws (PsychKG). Compulsory treatment occurs within psychiatric facilities of prison hospitals. Unlike Sweden, German rules do not make it necessary to send the prisoners to general psychiatric facilities if compulsory measures become necessary (Salize et al. 2007).

Occasionally, the patient's decision to refuse treatment results from a conflict relating to nonmedical issues: for example, when a prisoner goes on hunger strike to protest against a judicial or administrative decision. In this situation, the doctor should assess the state of health of the person concerned and subsequently make a detailed note in the patient's file to document that the individual has the capacity to understand the treatment proposed but has refused treatment on sound intentions after being given detailed information. Psychiatrists are regularly asked to assess the mental state of prisoners, especially to answer the question if the refusal is caused by delusions (e.g., to be poisoned).

The need for medical care of prisoners who persistently refuse food in order to make a protest is rare but challenging. Knowledge about the hunger strike quickly

spreads and gets into the political arena. Governments want to resist the demands, which often have political implications, but do not want prisoners to die. Pressure is therefore imposed on the prison health care staff, including psychiatrists, to keep the prisoners alive, if necessary, by force-feeding. However, a doctor must obtain consent from the patient before treating him. The only exception is an emergency when the patient is incapable of giving consent. Since the end stage of food refusal is coma, it is foreseeable that the patient will become incapable of giving consent. At that stage, doctors are allowed for intervening by artificial feeding to save the patient's life. However, this is not allowed if the patient has made it clear beforehand that he refuses interventions to prevent death (e.g., by an advance directive).

Disciplinary Measures

Mental health problems may be overlooked especially in prisoners who are psychotic quietly. The more behaviorally disturbed are often viewed as a disciplinary problem rather than as individuals with mental health needs (Birmingham 2004). Some of them are placed in disciplinary segregation instead of immediately receiving appropriate psychiatric care. Of particular concern are disciplinary measures which are coercive by nature. Mentally disordered prisoners are more likely to become the subject of disciplinary measures due to their misbehavior that may be caused by the disorder (Birmingham 2004; Morgan et al. 1993). It is well known that specific coercive measures (e.g., solitary confinement) are likely to aggravate mental disorders. Thus, it is crucial to assess the mental state of a prisoner prior to implementing such measures in order to avoid any additional harm. In some European countries, e.g., Germany, all prisoners for whom punitive or disciplinary measures are intended or all prisoners known to suffer from a mental disorder are assessed for their resilience before disciplinary measures are executed. In other European countries, such an assessment is not stipulated (Salize et al. 2007).

The participation of medical personnel in the administration of disciplinary measures raises considerable ethical problems: Discipline and punishment are security but not health issues, and therefore, the physician, who should be available to attend to the medical needs of prisoners under any form of punishment, has no role in deciding about the administration of such punishment, e.g., in certifying that a person is mentally fit to withstand such a punishment, and should not be available for the purpose of supporting the prisoner's capacity to sustain a punishment (WHO Europe 2009).

Somewhat surprisingly, in Germany, like in most European countries, disciplinary or coercive measures during imprisonment must be recorded but are not published, so that scientific analyses are not possible. Such records or files would be an essential tool for investigating the appropriateness of such measures, particularly in the case of mentally disordered prisoners. Because of the negative effects of disciplinary measures on the mental health – especially for mentally disordered patients – close confinement should be reduced to an absolute minimum and be replaced with one-to-one continuous nursing care as soon as possible. Unfortunately, in Germany, there is more isolation and observation by video than

one-to-one continuous nursing. In such cases, the prison psychiatrist is often confronted with ethical conflicts: Testifying acute suicidality in a mentally disordered prisoner without the possibility of adequate inpatient treatment means to produce a possibly traumatizing situation, particularly a situation of isolation with the requirement to undress or change clothes and to being exposed to video observation.

Legal and Organizational Frame for Dangerous, Mentally Ill, Nondelinquent Persons

Also nondelinquent persons with mental illness can be admitted to psychiatric institutions and treated there against their will, if they are acutely dangerous for themselves or for third persons. The civil commitment laws of the federal states of Germany (PsychKG or Unterbringungsgesetze) rule the compulsory admission and the compulsory treatment of this group of patients. Although each of the federal states of Germany has its own civil commitment law, they coincide in their core issues and differ only in some details.

Compulsory Admission to General Psychiatric Clinics

The civil commitment laws contain articles, which allow the commitment of mentally ill persons, who are acutely dangerous for themselves and/or for important legal rights of third persons. However, neither a mental illness alone, nor missing insight into the illness and the need for treatment are sufficient for compulsory admission. A compulsory admission has to be ordered by a court.

Compulsory Treatment

The civil commitment laws also allow for compulsory treatment of patients admitted to a psychiatric institution, but, as mentioned above, the Federal Constitutional Court has recently judged these regulations of two federal states as unconstitutional, and prompted the state parliaments to reformulate their laws so that compulsory treatments could be allowed, if they regarded the strict legal conditions, which have been formulated by the Federal Constitutional Court (Müller et al. 2012a). Several federal states are currently working on reforms of their civil commitment laws.

Only in cases of acute danger (e.g., if a patient tries to hurt or even kill someone), it is allowed to use compulsory treatments (Penal Code, Art. 34). Nevertheless, in most such cases, other measures will be preferable, e.g., fixation or isolation.

Compulsory treatments of confined mentally ill patients under custodianship can be allowed by courts according to the modified civil law. Therefore, a number of conditions have to be fulfilled: The patient is not able to consent to the necessary treatment; the physicians have tried to convince him; the treatment is necessary to avert considerable health detriments; the compulsory treatment is used as a last

resort treatment and its benefit-risk balance is positive. Compulsory treatments according to civil law can be allowed only for the patient's own benefit; they are no means to prevent harm from third persons.

Further Compulsory Measures

Besides compulsory medical treatments, a number of nonmedical measures are used either alternatively or additionally to compulsory medical treatment, in particular isolation, separation, fixation, mechanical restraint, and physical restraint. These measures are regulated in the civil commitment laws; they have not been questioned by the Federal Constitutional Court.

Measures to Avoid Compulsion

A rather new instrument for avoiding compulsive measures in states of dangerousness is the mental health advance directive. Advance directives are nowadays established for end-of-life settings, but they might also be suited to mental health settings. A patient with a chronic mental illness can specify her future preferences for treatment, should she lose the capability to make decisions. By way of example, patients can specify whether they prefer isolation, mechanical fixation, or medication, and where required, which drugs, the maximal dose of drugs, and the maximal period of drug application. According to a Cochrane study (Campbell and Kisely 2010), there are too few data available to make definite recommendations, but the preliminary results are promising: Patients given advance treatment directives committed less violent acts, needed less use of social worker's time, and showed greater improvement in their working relationship with their clinicians and were more likely to report satisfaction with their treatment. High intensity advance directives, such as joint crisis planning, may offer promise.

Conclusion and Future Directions

Generally, a patient-centered treatment which is orientated to the patients' needs and avoids restrictions as far as possible allows for reducing compulsory treatments to the minimum.

The mental health advance directive seems to be useful to avoid compulsive measures in states of dangerousness. Furthermore, if "permanently closed" wards are abolished and the doors of all treatment units are opened as often as possible, aggressive incidents, compulsory treatment but also absconding can be substantially reduced (Lang et al. 2010).

Relationship of Benefits to Risks in Psychiatric Research Interventions

58

Hanfried Helmchen

Contents

Abstract

The risk-benefit evaluation of a research intervention is only probabilistically possible and is open for contextual influences, because the criteria of benefits and of risks are often only insufficiently quantitatively defined. The question remains whether it is at all possible and, if so, how individual benefits and risks can be balanced against societal benefits and risks. Algorithmic attempts to structure the evaluation process should standardize the evaluation. However, for now, only a pragmatic solution will validate the result in three steps (researcher, ethics committee, potential research participant).

Introduction

Every physician must consider the expected benefits in relation to the potential risks of his/her diagnostic, therapeutic, prophylactic, etc., intervention

for the patient. This up to now mostly implicit estimation has become more explicit during the past decades by the medical obligation to inform the patient in order to gain his/her consent. This is particularly valid in the case of off-label use of interventions or quasi-experimental procedures in the individual patient, the so-called attempts at healing (Heilversuche). Moreover, especially in research interventions, the researcher has to consider explicitly his/her arguments for the acceptability, i.e., the justification and reasoning, of his/her planned research application to an ethics committee (Europarat 2005). Several regulations specify that the potential risk must have been assessed adequately and can be dealt with satisfactorily (World Medical Association 2008).

Without these prerequisites, a research intervention is not permissible even if a subject with the capacity to consent consents to participate. However, this does not mean that risky interventions or those without potential individual benefit cannot be justified ethically in consenting subjects, e.g., healthy volunteers in phase 1 trials. Thus, reasons must be given for an acceptable benefit-risk relationship.

But it is difficult to find an acceptable benefit-risk relationship,[1] or it will be seen as impossible: “risk-benefit ratios often cannot be calculated, even roughly; and that even if they could, ethical experiments don’t need to have favorable risk-benefit ratios” (Rajczi 2004). The final report of the American National Bioethics Advisory Commission reads as follows: “An IRB may approve a research proposal only if it judges that the risks are reasonable in relation to potential benefits. This judgment may be an IRB’s single most important and difficult determination, because it ensures that when research participants voluntarily consent to participate in a research study, they are offered a ‘reasonable choice’” (cit. Simonsen 2009). Unfortunately, as the report continues, “current regulations do not further elaborate how risks and potential benefits are to be assessed, and little additional guidance is available to IRBs” (Wendler and Miller 2007).

This has to do primarily with the estimation of benefits to risks in the participating individual. But it is also an estimation of the individual benefits and risks to those for society. However, there is a doubt that it is possible at all to estimate the relationship of these individual benefits and risks to the potential benefits and risks for society other than qualitatively and personally. But there is “not at all an operational criterion for the decision that this benefit or harm for the individual is of greater magnitude than benefit or harm for society. Furthermore, there is no way to calculate the social value against the individual risk without further assumptions.” (Wiesing 2011). Therefore, Hüppe and Raspe avoid terms which may “suggest a comparability of the extreme heterogeneous potentials of benefits and risks” (Hüppe and Raspe 2011).

[1] “The wording ‘fair balance’ is occasionally used by the European Court of Human Rights when there is a reasonable relationship between legitimate but conflicting interests, typically between the individual and the society at large.” (Simonsen 2009).

Example 1
Compare the potential societal benefit of sequencing the human genome for possible targets of therapeutic interventions with the (minimal) individual risk of participants for discrimination and stigmatization by a misuse of their individual genetic data. Ethically it seems important that on the one hand such research interventions are without potential individual benefit and, furthermore, the confidentiality of the individual genetic data cannot be guaranteed with certain (Maier et al. 2013), and on the other hand, it is not for sure that the modern sequencing methods will reach their promised objectives.

Example 2
The individual benefit of recovery from an illness as quickly as possible may clash with the social value of gain of knowledge if, e.g., the patient's recovery may be delayed because he/she belongs to a purely placebo group.

In these examples, the gain of general knowledge for the benefit of future patients as members of society can be understood as a social benefit (Emanuel et al. 2000).

Raspe relates the term "societal benefit" in a much broader sense to other "beneficiaries: the whole explanatory knowledge of medicine, population health, health insurance and their financial stability..." (Raspe 2012). However, to judge the relationship of such benefits to risks may be much more difficult than that between the defined benefits and risks of a specific medical intervention both for the individual research participant and the societal benefits and risks.

Furthermore, a basic difficulty exists insofar as potential risks and benefits can be determined only as probabilities, e.g., as "probable," "possible," or "not to be excluded." Moreover, these probabilities vary among individuals, e.g., with regard to every day risks, or among ethics committees. Due to the fact that unequivocal criteria of the extent of benefits and risks as well as clear algorithms for the evaluation of their mutual relationship do not exist (Rid et al. 2010), the justification of a benefit-risk relationship can be influenced by individual dispositions (characters or prejudice) as well as by the current social situation of the evaluator, the physician, the patient, the potential research participant, and members of the ethics committee (Rid et al. 2010). At least the evaluator should be aware of this and reflect such possible background influences on his/her preconceptions: e.g., a society-oriented evaluator (or the researcher) could estimate the societal benefit of the expected gain of knowledge more highly and the potential burdens of the proband less than a more individualistic or research skeptical evaluator (or treating physician) might do.

Rid et al. state six reasons for the unreliability of such intuitive judgments among others that they do not consider systematically existing empirical data and that they are subject to personal bias, e.g., by rating lower the risks of interventions familiar to

the evaluator than the risks of interventions with which he/she is not familiar, and that therefore the estimates of acceptable risks vary in a broad range among ethics committees (Rid et al. 2010; Shah et al. 2004).

Because of these difficulties of judgment, research ethics committees tend to avoid comprehensive evaluations of the risk-benefit relationship and focus on other aspects of the research project, such as the informed consent process, as Simonsen found in a 3-year observational study of Norwegian research ethics committees (Simonsen 2012).[2]

However, because researchers and ethics committees must estimate the benefit-risk relationship of a research project in order to account for legal regulations, they should communicate the reasons for their estimates with regard to their comprehensibility. And, where applicable, they should say that "defined risks are not acceptable, namely in the sense that they are not negotiable" (Wiesing 2011). In any case it is the task of the researcher to convey the significance of probabilities and particularly those of the benefit-risk estimation in a mode that can also be understood by the potential research participant. In view of the uncertainty of risks that can be calculated only as probabilities, decisions will be made logically statistically according to the prevailing opinion, but in fact however intuitively heuristically (Gigerenzer 2006). The question of whether such knowledge of the psychology of intuitive decisions will be helpful requires future investigations.

The evaluation of the acceptability of the benefit-risk relationship is specifically important in research interventions with patients whose capacity to consent is impaired by a mental illness, because the risk of exploitation of such vulnerable subjects may be larger than in patients who are competent to give informed consent. A careful evaluation also includes an understanding of the uncertainties in assessing potential benefits and risks that should be considered for both the individuals participating in research and other current or future patients (society).

Thus, benefits and risks are to be evaluated primarily with regard to individual subjects who participate in a research intervention. In cases with more than minimal risks on the individual level benefits and risks are to be considered with regard to society too.

> Also interactions have to be considered among individual and societal benefits and risks. This is valid not only for research interventions but also for everyday medical interventions. Thus, societal risks such as burdens on insurance companies should also be considered on the individual level, because, in order to save resources for the community, medical services may be applied only in an effective and economically efficient mode and their benefit must be proven according to the state of the art (SGB V) (Deutscher Bundestag 2010).

In order to make clear the determinants of such estimations, Rid et al. recently proposed a procedure for a standardized evaluation of risks, which will be considered in the following (Rid et al. 2010).

[2]Literature on the lack of rules and on the difficulties of benefit-risk estimates of research projects can be found in (Hüppe and Raspe 2011) and in (Rid et al. 2010).

Type, Magnitude, and Likelihood of Benefits and Risks

The comparability of benefits and risks as well as the evaluation of the benefit-risk relationship requires a:
- Definition of specific types
- Graduation (or even quantification)
- Estimation of the probability of occurrence of benefits and risks

Benefits

Individual Versus Social Benefit

The *social benefit* of clinical research in psychiatry consists in the gain of knowledge for the improvement of the treatment and care of mentally ill patients. Basically it can be seen as urgently desirable, because mental diseases are widespread and the need for research is great as opposed to the necessary scientifically proven knowledge for optimal psychiatric action. However, the estimation in the individual case depends:
- On the one hand upon the probability of an unequivocal gain of knowledge, i.e., upon the quality of the scientific method
- But on the other hand upon the relevance of the expected gain of knowledge for psychiatric action

Due to the conviction of liberal western societies expressed legally and also in the Declaration of Helsinki, § 6 (World Medical Association 2008) that no human being is obliged to donate himself/herself to society, the practice of clinical research will be dominated less by its societal benefit than by the individual benefit of the patients participating in research.

Individual benefit comprises both:
- The subjectively determined well-being in the sense of a self-experienced and self-evaluated benefit
- The more intersubjectively (“objectively”) evaluated “best interest” of the patient as a benefit seen from the outside, so to speak an objectively, externally judged benefit

This differentiation is significant insofar as in case of a patient not competent to consent, the substituted consent by an authorized person must be guided by wishes of the patient expressed beforehand, e.g., by an advance directive, for the well-being of the patient. If no information exists about such personal wishes, the substitute must decide in the best interest of the patient (Heinrichs 2007).

Patients themselves see the benefit of participating in research in that they will:
- Receive a better treatment that will be more effective than the available standard therapy or will act more quickly or will have fewer side effects
- Satisfy altruistic feelings of solidarity with other similarly ill patients (Rosenbaum 2012)

> Most respondents continue to participate in the ESPRIT study in hopes of benefiting personally. The majority also recognized that by participating in ESPRIT they were contributing to helping others; they experienced pride regarding this contribution and considered it an important reason to continue to participate. (Magnus and Merkel 2007; Wendler et al. 2008)

- Receive money or other advantages (Sofaer et al. 2007)

Further motivational factors are:
- To receive more information about one's own illness and its characteristics.
- To feel self-determined.
- The hope that other people will understand better their mental state.
- Particularly in the mentally ill without the capacity to consent, the motivation of the caretakers is important; this has been evidenced in research interventions which have aimed for an improvement of the quality of life of the patients and/or for an attenuation of the burdens of the caretakers (Connell et al. 2001; Mastwyk et al. 2002).

Specifications of Benefit

Benefit can be defined only in relation to something:
- *Societal* benefit of research is related to the gain of knowledge. In this case, the "essentiality" of the gain of new knowledge towards the existing knowledge plays an important role (s. below).
- *Individual* benefit, e.g., can be assessed as an attenuation of symptoms or of suffering or of an augmentation of the quality of life or functional improvement.

Compared with clearly defined and well-ascertainable phenomena such as some symptoms, it is more difficult to operationalize the attenuation or increase of more complex phenomena such as suffering or quality of life; but such an operationalizing would be a prerequisite or at least a support for the assessment of the size of the benefit. However, many of the following terms, which specify and grade benefits and risks by the dimensions of size and probability, are not clearly defined or are not at all definable and thus are open to subjective interpretations.

Such specifying criteria of benefit are:
- "Direct" or "immediate" benefit will be used synonymously. However, "direct" benefit can be understood as a causal effect of the intervention, "immediate" benefit by contrast as an effect in a timely connection. "Direct" suggests that "indirect" forms of benefit may also exist, e.g., if the development of a new effective therapy is based on the knowledge of the cause of the illness that was found during an earlier research intervention in a patient with an illness of long duration. "Few existing accounts disagree over how this crucial concept of 'direct' benefit should be defined. This disagreement raises concern over whether those who cannot consent, including children and adults with severe dementia, are being adequately protected." It is suggested "that the extant definitions of direct benefits either provide insufficient protection for research subjects or pose excessive obstacles to appropriate research" (Friedman et al. 2010, p. 60).

- "Therapeutic research" as potentially beneficial for the patient participating in research had been compared to "nontherapeutic research" without potential individual benefit. However, this distinction is questionable, because the border between both types of research is often not clear: "A therapeutic research study may prove that the experimental intervention is ineffective, in which case undergoing the experimental condition would be not beneficial to the subjects. Conversely, a non-therapeutic study may be associated with benefits for the subjects, such as more attention from health care workers. etc." (Welie and Berghmans 2006, p. 69). This is particularly valid with regard to the "therapeutic misconception," i.e., that the research participant misunderstands the research intervention as a mere therapeutic intervention (Vollmann 2000). Therefore, the ethically unequivocal terms "with" or "without" potential individual benefit should be preferred.
- As "collateral" benefit, a benefit will be termed that cannot be ascribed causally to the research intervention but to other aspects of the study performance and study participation, e.g., an "inclusion benefit" by an intensive medical monitoring (Hüppe and Raspe 2011).
- "Important," "essential," or "significant" benefit are particularly vague terms and are thereby open for different interpretations. Thus, the Explanatory Report (Nr. 87) to the Additional Protocol of the European Council defines "essential" as an "essential extension of the scientific understanding of a disease" (Europarat 2011). The circularity of this explanation shows the difficulty in defining the term "essential" clearly, unequivocally, and practically. Aside from a broad understanding of the contents of the field in which "essential" insights can be gained, i.e., new knowledge of causes, treatment, and prevention of a disease, the term "essential" itself remains unclear.

  Is it necessary for new knowledge, in order to be viewed as "essential":
  - To be not less than a breakthrough, i.e., knowledge that opens new possibilities for action?
  - To be a breakthrough only with an immediate impact or also with a delayed effect?
  - To be – with regard to formal criteria – proven at least and on which level?

    On the other side, the vagueness of such terms opens a necessary range for interpretations, because the newness of knowledge progress and its practical usefulness are difficult to judge and are only seldom quickly recognizable.
- Because it is the objective of research to gain new knowledge, every research surpasses an exclusively individual benefit and is oriented supraindividually. Insofar the extent of the individual benefit, i.e., the self- interest, must be related to the benefit for others, i.e., other person's interests ("Fremdnützigkeit"). Hence, the potential individual benefit (benefit, potential individual) is largest if the research participant can expect such benefit for himself/herself during the ongoing study (group 1 of the statement of the Central Ethics Committee of the German Board of Physicians (Zentrale Ethikkommission bei der Bundesärztekammer 1997)); it will be less in studies with only future benefit (group 2) and

will be at most questionable in research with expected benefit mainly for the group of patients to which the research participant belongs by age or disease (group 3). Such "group-specific" research will be differentiated from research with benefit exclusively for others (group 4).

In the framework of clinical research "group-specific" benefit as benefit for others means improved medical knowledge for the optimization of diagnostics, therapy, or care for other patients with the same disease or in the same age group. This can be the sole benefit of a research intervention with only questionable or no potential individual benefit for the participant of a research intervention, e.g., in a validation of a diagnostic measure or in a study of possible conditional or risk factors or causes of a disease. In order to prevent an excessive use of the term "group benefit," it has been proposed to define further beneficiaries not only by disease, age, and gender but additionally by the "inclusion and exclusion criteria on which the study is based" (Hüppe and Raspe 2011).

- The "size," "extent," "magnitude," or "strength" of a benefit however defined could be graded as "questionable," "slight or recognizable," or "unequivocal or strong."
- "Prospective" or "potential" benefit indicates an anticipation or expectation of a benefit. Because it is a determination of a likelihood, the occurrence of a benefit should at least be graded as "possible" or "probable."

Risks

If a subject participates in a necessary or even legally required research intervention for the benefit of all, he/she must be protected against the risks of this intervention. Protective norms are also related to gradings of risks.

Various normative rules describe the content, extent, and the mode of protection of research participants against risks, e.g., declarations such as the best known one of Helsinki in 1964 with the following revisions by the World Medical Association (World Medical Association 2008), national research laws, and particularly the first internationally binding instrument for biomedical research, the European Convention on Human Rights and Biomedicine (1997) (Europarat 1997) and its Additional Protocol (2005) (Europarat 2005).

Individual Versus Societal Risks

Individual Risks (*Risks, Individual*)

The term risk comprises both:

- Rather "objective" endangering of the individual research participant, e. g., with unwanted accompanying effects of the intervention, for example, unwanted side effects of an investigational drug or risks of blood taking for research purposes, but also prolongation of suffering or worsening of the disease due to withholding a specific treatment in a placebo group, in a broader understanding also

dispositions for unwanted effects such as (pharmaco)genetic or allergic inclinations belong to this group of risks.
- Rather "subjective" burdens and inconveniences, e.g., by the methodological rigor of the research procedure or feared risks of stigmatization especially in depressive or drug-dependent patients, which may demotivate potential research participants. Because of the subjective dimension of risks and unwanted effects, potential research participants should be examined particularly for their susceptibility to physical or psychic burdens that may be related specifically to the research intervention.

  Thus, e.g., the magnetic resonance imaging (MRI) has no objective risks, but may indeed – in claustrophobic patients – become a subjective burden that leads to a termination of the intervention. For risks that are specific for the intervention and that have large relevance for the further life of the patient, he or she must be informed independently of the probability of occurrence.

Societal Risks (*Risks, Societal*)

However, societal risks should also be considered, e.g., if research interventions have considerable risks or do not follow precisely the normative prescriptions and thereby lead to incidents that undermine the necessary trust of the public or of potential research participants. This can protract or even prevent the recruitment of research participants. But not executing a research project may also present a societal risk, e.g., if the lack of knowledge must urgently be eliminated, in order to contain and treat an acute threat to health such as an infectious epidemic or to substitute an ineffective measure by an effective one.

Specifications of Risks (*Risks, Specifications of*)

- Magnitude, extent, or strength of risks are graded by a broad range of terms, such as "without the danger of injury," "minimal risk," "minor increase of minimal risk," "not negligible risks," "serious risk for health," "potentially irreversible damage," and "risk of inacceptable dimension" (Helmchen 2002).
- Absolute upper limits of risks are irreversible impairments and death. Standard upper limits for research with patients incompetent to give informed consent are "no more than minimal risk" or with minors even "minor increase of minimal risk" (Wendler 2008).
- "No more than minimal risk" is a decisively limiting criterion for research with patients incompetent to give informed consent. However, there are different interpretations of "minimal risk":
  – US regulations permit ethics committees to approve a research intervention in patients incompetent to give informed consent only if "it poses no more than 'minimal' risk, defined as the risks encountered in daily life or during the performance of routine examinations or tests" (Wendler 2008, p. 467). But "in the absence of empirical data, IRB members may assume they are familiar with the risks of daily life and with the risks of routine examinations and tests and rely on their own intuitive judgment to make these assessments.

Yet intuitive judgment of risk is subject to systematic errors, highlighting the need for empirical data to guide IRB review and approval of pediatric research...Current data on the risk of mortality in healthy children suggest IRBs are implementing the federal minimal risk standard too cautiously in many cases" (Wendler et al. 2005). On the other hand, this concern has led to a warning against a softening of the "minimal risk" concern (Gefenas 2007).

– Furthermore, standards of minimal risk vary with regard to the risks of everyday life with age (Wendler 2009). With children there are other standards than with older persons. Because of these difficulties, it has been proposed that the standard of everyday life be eliminated (Resnik 2005).
– However, there has been an attempt to objectify the standard of everyday life by considering the magnitude and likelihood of injuries in sports and in car driving, i.e., two common everyday activities (Rid et al. 2010).

> With regard to the criterion "routine examinations," the Central Ethics Committee of the German Federal Board of Physicians commented that the standard of minimal risk is present "e.g., when taking small amounts of body fluids or tissue in the framework of diagnostic measures or surgery without additional risks for the patient. Defined somatic investigations also belong to this standard (e.g., sonography, transcutaneous tissue measurements) or psychological investigations (e.g., interviews with questionnaires, tests, observations of behavior)" (Zentrale Ethikkommission bei der Bundesärztekammer 1997).

- "Minor increase above minimal risk": this standard was introduced in the USA for research with children. However, it remains unclear what "minor increase" means (Wendler and Emanuel 2005). Accordingly other countries did not follow this line. Also the ambiguity of this criterion has led ethics committees to different interpretations and to a call "for a national consensus on the interpretation of federal regulations" (Fisher et al. 2007).
- Research without potential individual benefit in patients incompetent to give informed consent will be seen either – according to German law – as inadmissible or – according to the European Convention on Human Rights and Biomedicine (1997) – as ethically acceptable only as an exception and when limited by the criterion "no more than minimal risk," if at least a group-specific benefit can be expected and if the consent of the research participant will be substituted by an authorized person.

Proposals for Grading

During the past 15 years, the grading of benefits and risks has been intensified more systematically:

- Thus, a taxonomy of benefits and risks according to their magnitude or severity has been proposed (Helmchen et al. 1995) (see Table 58.1).
- The following table had been developed as an advanced categorization that contains the essential variables of evaluation of the German Drug Law (Deutscher Bundestag 2004) (see Table 58.2).

Table 58.1 Taxonomy of benefits and risks according to their magnitude (Translated in English and modified from Helmchen and Lauter 1995, S. 47f.)

Risks
1 No or at most minimal risk
2 Mild increase of minimal risk
3 Unequivocal more than minimal risk
4 Risk with irreversible consequences
Benefits
1 No or at best questionable benefit
2 Benefit only for the public good (benefit *without* potential individual benefit)
a. Only by extension or safeguarding of existing knowledge
b. By qualitative new knowledge
3 Benefit for both the public good and the individual research participant (intervention *with* potential individual benefit)
a. Only by quantitative improvement of existing standards
b. By qualitative innovative treatments

Table 58.2 Grading of risks and the essential evaluation variables of the German Drug Law (AMG) (Translated in English from Terwey (2007), S. 138, Table 24)

	Risk	Vulnerability	Chance	Scientific quality GRADE	Evidence SIGN
A	No risk	Not vulnerable	Patient	High	A
B	Minimal risk	Vulnerable	Group specific	Moderate	B
C	Minimal increase above minimal risk	Children	Science Short termed	Low	C
D	More than minimal increase above minimal risk	Patients who are not competent to give consent	Science Long termed	Very low	D

GRADE grading of recommendations assessment, development and evaluation
SIGN Scottish Intercollegiate Guidelines Network
Each of the five columns shows an order from a lower to a higher grade or from general to more specific items. However, the columns should not be seen as completely correlated to each other. Thus, e.g., in the risk column lines C and D are related only to children. "Chance" means the objective of the research intervention, i.e., the chance of a benefit for the individual research participant or at least for the group of patients with the same age or illness condition of the research patient, or the research results are expected to be applied currently (short termed) or are more of a basic nature with perhaps applicable findings in the future (long termed)

- Rid et al. (2010) produced after consultation with experts an empirically based scale of seven grades of injury and illustrated each grade with specific examples of the consequences of the injury and its duration and treatability (Rid et al. 2010) (see Table 58.3).
- Recently further proposals have been published in order to adapt control and monitoring of clinical research to the level of risk. Thus, a model of risk

Table 58.3 Magnitude of harms scale with illustrative examples[a] (From Rid et al. (2010) with permission of JAMA Copyright © (2010) American Medical Association. All rights reserved)

Examples and details of harms			
Examples of harms by magnitude	Effect/disability	Treatment	Duration
Negligible			
Mild nausea	Discomfort; can interfere with ability to pursue some minor life goals (e.g., eat)	May require medication	Minutes to several hours
Skin bruise or abrasion	Mild pain	Can require cleaning and coverage	Bruise or abrasion pain, minutes to several hours; healing, $\leq$10 days
Small			
Headache	Moderate pain, inability to pursue some minor (e.g., 1 day hiking) and some major (e.g., attend school) life goals	May require medication, rest, or both	Hours
Common cold	Discomfort, inability to pursue some minor (e.g., visit museum) and some major (e.g., work) life goals	May require medication, rest, or both	Several days
Moderate			
Uncomplicated bone fracture	Moderate pain, inability to pursue some minor life goals (e.g., play sports)	Requires some medication and wearing a cast	Fracture pain, hours; recovery, weeks to months
Moderate insomnia for 1 month	Annoying experience, inability to pursue some minor (e.g., meet friends) and some major (e.g., work) life goals	Can require lifestyle changes and medication	Weeks intermittently

Significant			
Ligament tear of knee with permanent instability	Moderate pain that interferes with pursuing some minor life goals (e.g., exercise); permanent instability precludes vigorous exercise and requires adaptation (e.g., seek new types of exercise)	Requires surgery and rehabilitation	Tear, hours to days; rehabilitation time following surgery, weeks to months
Intensive care for several weeks (assuming no sequelae)	Often intense pain and physical exhaustion, inability to perform activities of daily life and to pursue essentially all minor and major life goals		Weeks
Major			
Psychotic episode	Terrifying distortions of reality, changes in personality that undermine relationships, precludes performance of daily life activities and many minor and major life goals	Requires medication, can require adaptation of some major life goals (e.g., work)	Weeks to a month
Rheumatoid arthritis	Daily episodes of serious pain and permanent stiffness, unable to pursue some minor (e.g., vacation) and some major (e.g., work) life goals, sometimes unable to perform some activities of daily life	Requires aggressive medication, physiotherapy, requires major adaptation	Years
Loss of finger	Destabilizes hand, interferes with many activities of daily life, interferes with some minor and major life goals, requires adaptation, distressing transition period	None	Permanent

(*continued*)

Table 58.3 (continued)

Examples and details of harms			
Examples of harms by magnitude	Effect/disability	Treatment	Duration
Severe			
Major depression	Depressive episodes with hopelessness/worthlessness, loss of interest in usual activities, isomnia, and eating; can preclude performance of some daily life activities and some minor and major life goals; often baseline anxiety and low mood	Requires medication; requires adaptation of some major life goals (e.g., relationships)	Decades
Paraplegia	Inability to perform some activities of daily life, inability to pursue many minor (e.g., hiking) and some major (e.g., having children) life goals, often distressing transition period	Requires daily support and close clinical observation; requires major adaptation	Permanent
Catastrophic			
Severe dementia	Precludes performance of daily life activities and essentially all minor and major life goals, adaptation impossible, distressing transition period	Requires full-time care	Permanent
Death			

[a]Important factors that influence the magnitude of a harminclude associated experience (no sensory, nuissance, uncomfortable, distressing, suffering); burden of efforts to mitigate condition (low/moderate/high, weeks/months/permanent); inability to perform activities of daily life (partial/complete); inability to realize life goals (minor/major life goals, some goals in one category/some goals in both categories/all goals in one or both categories); duration (minutes/hours/day/weeks to months/years/permanent, intermitten/continuous); potential to adapt to new (residual) condition (minor/moderate/major adaptation, impossible to adapt); and burden of adaptation period (low/moderate/high). The examples were chosen based on input from 43 international experts in clinical research, research ethics, and risk assessment. The example have an illustrative function to show how the harm scale might be applied. Factors not mentioned in the description of an example are considered not relevant. It is assumed that the given harms occur in otherwise healthy, normal, average individuals (adults), which implies that the selected examples might fall into a different category on the harm scale in individuals who are not healthy, normal, or adults. No examples of economic or social harms are given due to their strong context dependence

estimation was introduced in 2010 into the discussion of the revision of the EU directive on clinical research that proposes to determine the two dimensions of severity and likelihood of impairments of health for defined groups of risks (sponsor and experience; product class; stage of development: pre- or post-marketing approval; scientific newness; characteristics of patients; method of trial) (Hartmann and Hartmann-Vareilles 2012). The German ADAMON project (Brosteanu et al. 2009) and the British community project(MRC/ and DH/ 2011) provide risk-adapted monitoring and control of clinical trials in three classes of risks with different intensity of control (and the bureaucratic effort).

To date, however, such proposals up to now are almost nothing more than constructs that can at most be useful for a rough structuring of the evaluation of the acceptability of benefits and risks of a research intervention and particularly of their relationship to each other. How much they can indeed achieve needs empirical validation.

Empirical Procedures for the Evaluation of the Benefit-Risk Relationship

- In contrast to the abovementioned proposals, such an empirical study of a more differentiated three-stage taxonomy was done ex post from all research applications of the year 2006 at the university hospital in Lübeck (Hüppe and Raspe 2011):

> "At the first step of analysis the identified consequences were differentiated according to their effects (positive or negative) in chances of benefit and risks of injury (with regard to addressee, relation to the study, relevance, extent, likelihood of occurrence, start of occurrence, sustainability, level of evidence)." "The second step of the analysis outlines the chances of benefit and risks of damages with regard to the respective addressee or concerned person into three partial quantities": potential self- benefit or self-injury; group benefit or group injury; benefit for others or injury for others. In step 3 of the analysis the detailed assessment of the features of individual chances of benefit and risks of injury" with regard to the criteria named under step 1 was carried out. Subsequently it was stated by two steps of balancing "whether the entire balance yields a net benefit"." In order to reach a concluding positive point balance a net benefit must be found." Such a "proceduralisation of the analysis of chances and risks can increase the transparency of the performed processes of analysis and comparison. The communication among researchers and ethics committees and among the members of the ethics committee will be facilitated in controversial research projects, the standardization and harmonisation of the consulting processes of the ethics committees will be supported.

- Recently the estimated risks of two research interventions, an allergy test and a liver biopsy, were compared with empirically assessed risks of everyday activities. In the first example, the magnitude and the likelihood of occurrence of the risks of allergy testing are below those of comparable everyday activities (e.g., sports or work), i.e., seem to be acceptable (Fig. 58.1).

However, the liver biopsy as a research intervention is ethically questionable because some of its risks are above comparable everyday activities (Fig. 58.2).

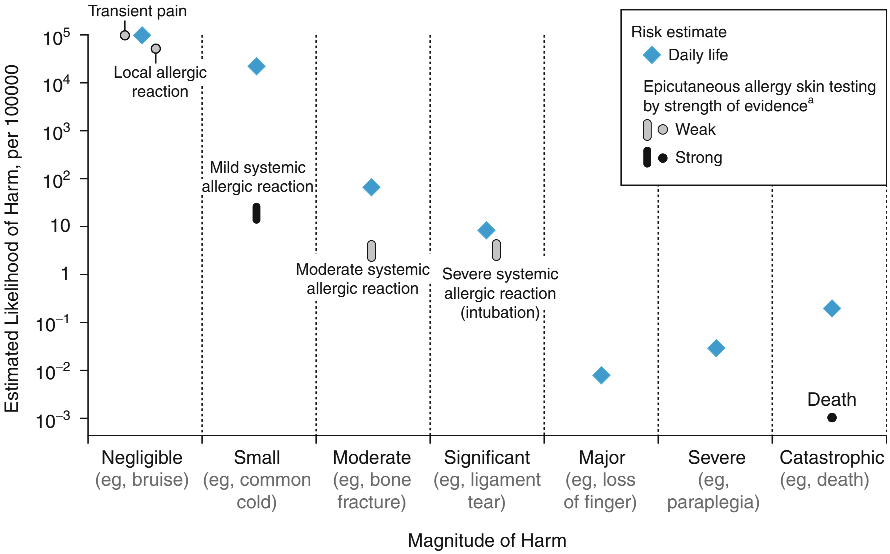

Fig. 58.1 Estimated risks of epicutaneous allergy skin testing (per 100,000): transient pain (negligible), approximately 100,000; local allergic reaction (negligible), approximately 50,000; mild systemic allergic reaction (small), 11–30; moderate or severe systemic allergic reaction (moderate or significant), 2–5; and death (catastrophic), approximately 0 (1 case report). Daily life risks in the United States (per 100,000): bruise (negligible), approximately 100,000 (all age groups); common cold (1 day [small]), approximately 22,000 (children); bone fracture or dislocation (surfing contest [moderate]), approximately 70 (adults); complete ligament tear of knee (sports practice [significant]), approximately 8 (adolescents); loss of 1 finger (workday in service sector [major]), approximately 0.008 (adults); paraplegia (day of skiing [severe]), approximately 0.03 (all age groups); and death (riskier car trip [catastrophic]), approximately 0.2 (adolescents/adults).[a]Span of elongated *data markers* indicates range of estimated risk (From Rid et al. (2010) with permission of JAMA Copyright © (2010) American Medical Association. All rights reserved)

This is a considerable step towards an empirical foundation of risk assessment. However, it is an open question whether it will gain acceptance because it is a very elaborate procedure.

Contextual Influences

An acceptable or reasonable benefit-risk relationship is understood usually as a justified relationship between benefits and risks. At the same time, it should be considered that the estimation of a benefit-risk relationship as justified also depends upon normative values.

Example

In studies with potential individual benefit but more than minimal risks, e.g., trials of new methods of vaccination, it must be decided whether the benefit-risk relationship is ethically acceptable in patients not competent to give

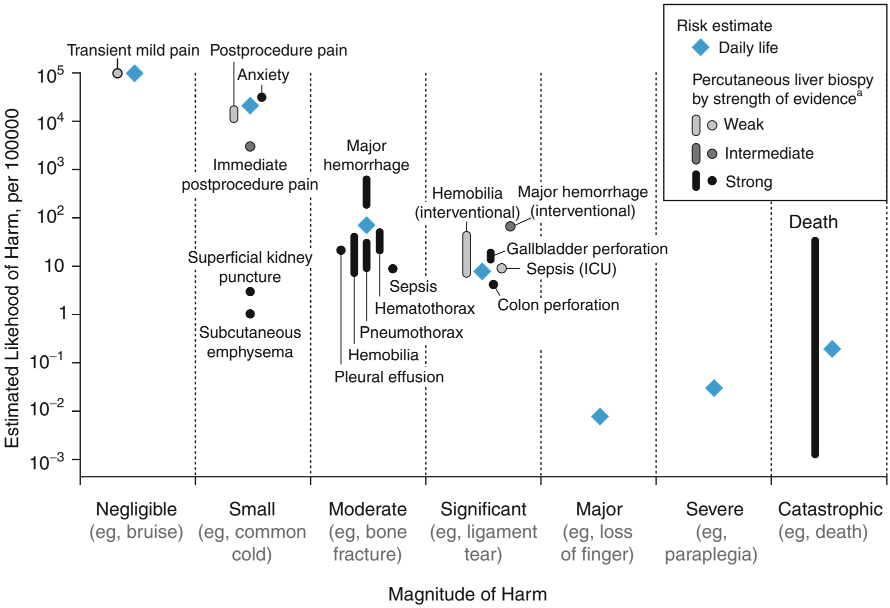

Fig. 58.2 Estimated risks of percutaneous liver biopsy (per 100,000): anxiety (small), 31,000; transient mild pain (negligible), approximately 100,000; immediate postprocedure pain (small), approximately 3,000; postprocedure pain (small), approximately 10,000–20,000; superficial kidney puncture (small), 3 subcutaneous emphysema (small), 1 pleural effusion (moderate), 21 hematothorax (moderate), 18–63 pneumothorax (moderate), 8–35 major hemorrhage requiring transfusion (moderate), 160–733 hemobilia requiring conservative treatment (moderate), 6–50 sepsis requiring antibiotic treatment (moderate), 9 major hemorrhage requiring interventional radiography/surgery (significant), 67 hemobilia requiring interventional treatment (significant), 6–50 sepsis requiring intensive care unit (ICU) treatment (significant), 9 gallbladder perforation (significant), 12–22 colon perforation (significant), 4 death (catastrophic), 0–40. For daily life risks see Figure 58.1 legend.[a]Span of elongated *data markers* indicates range of estimated risk (From Rid et al. (2010) with permission of JAMA Copyright © (2010) American Medical Association. All rights reserved)

informed consent and with currently untreatable disease conditions such as advanced stages of Alzheimer disease (analogous to the reasoning for experimental treatment in patients with final stages of cancer). Some family members might view the risk of burdens for the patient as considerable and are not convinced of the chance of a remission and therefore hope for a peaceful end for the patient; other relatives – in harmony with a possible advance directive or presumptive will of the patient – or also members of the ethics committee might estimate the potential benefit of an attenuation of symptoms or a prolongation of life to be much greater than the potential burdens.

Thus, for now it remains largely a personal evaluation of the participants judging the ethical acceptability of a research intervention. This evaluation is filled with uncertainties and is thereby open to contextual influences. But "what cannot be objectified can at least be controlled by procedures: one attempts to distribute difficulties onto several shoulders and hopes that the collectivity of judgments may lead to a result that is more acceptable. However, the basic difficulties of a balance between benefits and risks are not solved by this but are only regulated by procedure" (Wiesing 2011).

In order to control and to minimize these contextual influences, a three-step procedure will be formulated here:

1. The *researcher* must give his/her reasons for considering that the relationship of potential risks and burdens to the expected benefit of a planned research project is acceptable, i.e., that it is reasonable and justified.
2. The appropriate *ethics committee* must investigate this relationship and the evaluation of the researcher with regard to ethical and legal norms, if necessary with additional professional expertise. It should communicate its reasons – at least in research with patients not competent to give informed consent – not only in cases of rejection but also in cases of approval of the research plan and particularly with regard to the ethical argumentation of the researcher.
3. Finally the *potential research participant* or his/her authorized substitute must evaluate the reasons of the institutionally acceptable established benefit-risk relationship of the planned research intervention with regard to his/her own idiosyncrasies, values, and interests; after that he/she can consent if he/she feels that the benefit-risk relationship seems to be acceptable for himself/herself.

Conclusion

The evaluation of the benefit-risk relationship of a medical research intervention is only probabilistically possible and is open for contextual influences, because the criteria of benefits and of risks are often only insufficiently quantitatively defined. Whereas in a medical standard intervention the benefit-risk estimation is focused almost only on the individual, in a research intervention the societal benefit-risk evaluation must be added. The question remains whether it is at all possible and, if so, how individual benefits and risks can be balanced against societal benefits and risks, particularly if the research intervention contains more than minimal risks.

Only in the past decade researchers have begun to investigate determinants of the benefit-risk evaluation in ethics committees, to develop evaluation procedures (Curtin and Schulz 2011), and to systematize in a framework (Rid and Wendler 2011). Algorithmic attempts to structure the evaluation process should standardize the evaluation. However, for now only a pragmatic solution will be possible that will validate the result in three steps (researcher, ethics committee, potential research participant).

Contents

Abstract

In this section, we provide a comprehensive overview of the Ethics in Neurosurgery from the basic concepts of morality and ethical theory to the emergence of neuroethics. We further discuss development of new ethical dilemmas as technological advances come into clinical use and how general and medical society should be gathered in that ethical discussion.

The concept of morality addresses what is and is not socially acceptable. Morality deals with social conventions in terms of what is considered right or wrong, based on an implicit consensus among members of a specific community. Ethical theory, in turn, refers to an analysis of morality, the study and understanding of its nature, as well as its function (Beauchamp and Childress 1994). Medical ethics refers to the

study of morality as applied to medicine. The analysis of moral issues in terms of their relationship to professional behavior has led to the creation of professional ethics codes, among them the code of medical ethics, in order to guide and to create norms of conduct for medical practice. In this context, recent advances in neuroscience have sparked the creation of a new subdivision of this field, neuroethics.

The terms proposed by the codes of professional ethics may vary from country to country, but, in general, they support principles of autonomy, of beneficence, of non-maleficence, and of justice. Of the four principles, the principle of autonomy is perhaps the one most discussed in the literature about ethics, especially in the literature about the doctor-patient relationship and obtaining informed consent (Faden and Beauchamp 1986). Respecting patients' autonomy is one of the pillars of modern bioethics in the West. Autonomy recognizes the people's right to make decisions about their own treatments, free from any pressure or manipulation (Beauchamp and Childress 1994).

This attitude towards the principle of autonomy stands in opposition to the classic paternalist model, in which the doctor alone makes all the decisions. Through the principle of autonomy, patients have the right to receive clear information about their treatment and to make decisions based on their own beliefs and values. The doctor should help the patient to make choices and avoid coercion and persuasion, beyond providing relevant information in a comprehensible way, encouraging questions, and clarifying the management options that are available (Etchells et al. 1996b). Thus, autonomy can only be fully exercised when doctors fulfill their role to provide information. Establishing a good doctor-patient relationship is fundamental to any therapy's success, in the sense that the doctor should know and respect patient's expectations. The professional's goal should be one of kindness, considering that patient's interests and well-being come first. However, patients' expectations can vary, and the way in which any particular doctor deals with the questions involved in the therapeutic process may be very individualized.

There are many studies about patient preferences in the decision-making process. The results vary and are correlated with cultural, demographic, religious, and socioeconomic characteristics (Delgado et al. 2010; Coulter and Jenkinson 2005; Levinson et al. 2005; Robinson et al. 2001; Bruera et al. 2001; Pang 1999; Blackhall et al. 1995). Not all patients want to take control of the issues involved in their treatment. Some prefer a participatory model of decision-making and ask for the doctor's involvement, while others transfer their decisions to someone they trust (Delgado et al. 2010; Coulter and Jenkinson 2005; Levinson et al. 2005). In other words, if patients want to, they can delegate responsibility to a member of their family or ask for advice from the doctor, without this constituting a violation of their autonomy (Etchells et al. 1996; Lazar et al. 1996). Preferences also vary when research is performed on healthy or sick people and may depend on the nature of the illness itself (Delgado et al. 2010; Ruhnke et al. 2000).

Informed consent is an instrument that, when applied properly, guarantees the full exercise of autonomy. Originally, the term was referred to obtaining the patient's consent to perform a procedure. This consent might be verbal or via a form signed by the patient called a consent form, which these days fulfills

a purpose additional to its ethical one, having acquired legal value, as an instrument of protection. Doctors, however, still have an obligation to inform, and the patient's right to receive clear information should not be viewed merely as protection against potential litigation.

Some publications in the area of neurosurgery have considered patients' increased participation in the way the treatment itself is conducted as a violation of the traditional doctor-patient relationship. Moreover, the legal focus given to the application of terms of consent can cause neurosurgeons to "hyper-inform" their patients, as a "matter of safety" (Schmitz and Reinacher 2006). Doctors need to develop a good relationship with their patients so they can know and understand their expectations. This can be achieved with an honest conversation, in which patients are encouraged to resolve specific questions, but also by presenting a consent form giving the opportunity for the doctor to get to know patients better and the sociocultural context into which they are inserted.

Because of the need to guide neurosurgeons through contemporary ethical dilemmas, the World Federation of Neurosurgical Societies developed a statement of ethics in neurosurgery (Umansky et al. 2011). The document presents a set of directives about good practice in neurosurgery, with a special focus on maintaining a good relationship with patients and their families. It emphasizes that the surgeon's duty is to listen to patients, to respect their choices, and to clarify any doubts. The neurosurgeon has the responsibility to clearly inform and to obtain patients' consent before performing surgical procedures. The importance of good communication with family members, of respecting cultural differences, and of the need to act with kindness is all themes that the document broaches. In addition, the text underscores the relevance of good clinical practice and the need for doctors to continually update their knowledge and studies, as well as exercising care in adopting new technologies that have not yet been scientifically proven. The statement of ethics includes a discussion of what constitutes excellence in clinical practice and reminds us that, at a time when technology is constantly changing, human relations cannot be neglected.

Recent progress in neuroscience and the increased understanding of the nervous system's physiology have led to new ethical dilemmas. The brain has come to be understood as the organ in which the essence of our individuality resides. We increasingly understand our personality, our feelings, our behavior, our memories, and our perceptions as derivatives of brain function. Research in neuroscience challenges the very concept of what human nature is (Illes and Bird 2006). In this context, neuroscience offers a unique possibility to access the human brain. While basic advances in cognitive neuroscience and brain imaging have promoted a potential application in clinical practice and in neurosurgical research, the access to the brain that is made possible by neurosurgeons offers a chance to achieve significant advances in cognitive neuroscience (Tatagiba et al. 2007).

In practical terms, we can use the example of the awake surgery for resecting brain tumors. The distinctive feature of this type of surgery lies in the ability to improve tumor resection, preserving adjacent areas involved in cognitive function. Since various cognitive functions, such as language, memory and orientation, and

perception, can be tested during the operation, anthropological questions arise. What functions are really essential to being "human"? What functions make up the patient's individual personality? Making a hierarchy of these cognitive functions prior to the operation may be necessary in order to explicitly determine what the operation ought to preserve. This process conjures up other questions; are there cognitive functions that should not be damaged in some way during surgery? Or how does one make a decision when tumor resection might affect memory or language? Or, again, is an almost total tumor resection associated with a discrete reduction in memory preferable to a total resection with more significant cognitive damage (Clausen and Gharabaghi 2007)?

Neuroethics has arisen from the need to study the ethical, legal, and social implications of neuroscientific advances. The existence of functional exams allowing for the identification and location of complex thought processes, devices for deep brain stimulation, medical treatments and operations for psychiatric illnesses, and treatments for degenerative diseases with stem cell transplants are some of the challenges that neuroethics faces today (Lombera and Illes 2009). Thus, neuroethics is not simply a branch of bioethics, but a new science that deals with the definition of what it means to be human, with free will and self-knowledge (Levy 2011).

Therefore, the discipline of neuroethics can be subdivided into two branches: the ethics of neuroscience and the neuroscience of ethics. The *ethics of neuroscience* is the application of ethical principles to the studies and technologies developed by neuroscientists. The *neuroscience of ethics* involves what studying the mind tells us about the nature of morality (Roskies 2002).

One of the new ethical challenges prompted by scientific progress is the possibility for cognitive control through drugs or brain implants. The use of memory-modifying technologies seems a promising way to treat victims of post-traumatic stress. Using beta-blockers has allowed us to edit our memories. Since our past is a part of how we construct our identity, to what degree is the use of these new technologies socially acceptable (Erler 2011)? Methods to pharmacologically edit memory may be justifiable in the case of survivors of traumatic events, but using them in indiscriminate or "cosmetic" ways is discouraged (Erler 2011). We can enhance memory and attention pharmacologically by using modulators of AMPA glutamate receptors (*α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid*). Using neural implants to modulate brain function is another facet of external control over cognitive function. These new instruments bring with them moral dilemmas that demand a broad debate from the scientific community and broader society (Illes and Bird 2006).

The attempt to obtain surgical control of the complex mechanisms involved in cognition and the nature of our thought processes is not new in the history of medicine. Psychosurgery began in the early twentieth century, with Egas Moniz's development of the frontal lobotomy and Freeman's popularization of it (Hollingham 2009). The initial enthusiasm for the technique and the media attention paid to it led to an excess number of surgical indications, which only stopped after scientific publications about its harmful effects began to appear.

This historical example shows the importance of having a philosophical debate about the moral and ethical implications of every technological advance before popularizing it (Gilbert and Ovadia 2011). At the moment, the media has been heaping praise on deep brain stimulation devices, whether to treat psychiatric disorders or to control movement disorders, creating a natural demand for these new technologies, which society views with extreme optimism. Deep brain stimulation is, nevertheless, an invasive procedure that can lead to side effects in terms of cognitive behavior – and one whose mechanism is not entirely clear. It should only be indicated after a careful analysis of the moral questions involved (Gilbert and Ovadia 2011).

On the whole, neuroscience is a constantly changing field. As medical knowledge progresses, it creates new concepts and modifies clinical practice. In today's world, hospitals are incorporating new technologies on an almost daily basis, more quickly than ever before. The result of this state of constant change is that doctors constantly need to learn new techniques. As they are incorporated into the profession, new technological advances bring new ethical dilemmas. Society and the scientific world must maintain a continuous dialogue about the moral implications of these new technologies. Adopting health policies that meet the basic principles of bioethics depends on this debate.

Neurosurgery: Past, Present, and Future 60

Marcos Tatagiba, Odile Nogueira Ugarte, and Marcus André Acioly

Contents

Abstract

The practice of neurosurgery as we know it today is the result of centuries of evolution. Progress does not occur in a linear and methodical way, but rather in many cases stems from repeated episodes of trial and error. Although intellectual curiosity and the investigative spirit have been present throughout history, years of darkness and stagnation often follow fruitful periods of innovation. In this chapter, we provide an overview of the history of neurosurgery, from trepanations in the Neolithic period to the modern integrated operating rooms of today, with some considerations of the future prospects of the field.

The Past

The oldest neurosurgical practice we know of is trepanation, a term derived from the Greek word *trypanon* (borer), which involves making openings in the cranium by removing bone fragments. Trepanned crania have been found on every continent, with the oldest known samples being found in the Ukraine dating to the Mesolithic period (Carod-Artal and Vázquez-Cabrera 2004). The fact that trepanation was commonly practiced by civilizations across the globe says a lot about human nature. Different societies that were not in communication with one another, as far as we can tell, nevertheless developed similar cranium perforation techniques. But what was the goal of these primeval surgeries? We believe that people performed trepanations for a variety of motives, such as for ritualistic purposes or for religious or therapeutic reasons. Instances of postmortem trepanations that enabled people to use bone fragments as amulets have been found in France (Liu et al. 2003a).

In South America, a vast collection of trepanned crania that were preserved by the arid climate of the Peruvian coast have been uncovered. Approximately 5–6 % of the 10,000 mummies found in Peru show evidence of trepanations, including many which exhibit signs of bone remodeling, indicating that the person survived the procedure. Archeological findings come from the Paracas, Nazca, Chimú, and Huari cultures as well as from the Incan empire (Carod-Artal and Vázquez-Cabrera 2004). These primitive surgeons apparently had some empirical knowledge and had learned to avoid perforating dura mater sinuses and areas covered with muscles, thereby avoiding hemorrhage (Andrushko and Verano 2008). Pre-Columbian cultures developed a variety of trepanation techniques, including circular incisions, scraping, transverse cuts, and perforations, that were executed with the help of chisels made of obsidian, silex, and *tumis*. The *tumi* was a T-shaped instrument with a semicircular blade that is the symbol of Peruvian medicine today. Most Peruvian trepanations were located on the left side, in the temporoparietal area, probably in order to treat lesions caused by hand-to-hand combat with a skilled right-handed opponent (Andrushko and Verano 2008; Liu et al. 2003a).

Surprisingly, a group of Peruvian neuroscientists performed two surgical procedures in the 1940s and 1950s using sterilized pre-Columbian instruments. Whatever the moral and ethical implications of these acts, they did prove that it was possible to perform trepanation using primitive instruments (Carod-Artal and Vázquez-Cabrera 2004; Marino and Gonzalles-Portillo 2000).

The oldest known medical text to contain references to the practice of neurosurgery is the Edwin Smith Papyrus, given this name because Edwin Smith, an American living in Egypt, acquired it in 1862. The papyrus text dates from 1700 B. C., but it is actually a copy of an older text, from around 3000–2500 B.C., by an unknown author. The papyrus contains 48 surgical cases, each of which includes a description of the exam, diagnosis, and treatment. Of these, 27 were cranial lesion cases (Feldman and Goodrich 1999).

Hippocrates (460–377 B.C.), whose oath is mechanically repeated by students today, is considered the father of modern medicine. Hippocrates developed the

concept of careful observation applied to clinical practice and emphasized the importance of a detailed anamnesis. Based on his observations of numerous cranial traumas, most stemming from battles, Hippocrates wrote his *De Capitis Vulneribus*, a treatise about the diagnosis and treatment of cranial lesions. His system for classifying fractures covered five subtypes, with the treatment indicated being based on lesion type rather than the patient's symptoms. This practice persisted for a long time until the development of the concept of cerebral localization. Hippocrates argued against trepanations for depressed skulls and comminuted fractures, probably because the objective of trepanation was to create a drainage opening for blood or fluid. Hence, since the fracture had already created such an orifice, these cases would not have required trepanations. Hippocrates saw suppuration as a natural and desirable process for wound healing; this concept remained unaltered for many years (Panourias et al. 2005).

Because dissection was taboo at that time, Hippocrates's observations came from clinical practice. Herophilus (335–280 B.C.) performed the first methodical and regular dissections of the human body as an object of anatomical study. He not only dissected cadavers, but was also adept at vivisecting criminals. Herophilus cruelly contravened the limits of morality and humanity, but he made an unparalleled contribution to anatomical studies. Herophilus provided a detailed description of the dura mater sinuses (*torcular Herophili*) of the ventricular system and of the choroid plexus. He contradicted Aristotelian teaching by proclaiming that the brain was the home of the soul. He differentiated tendons from nerves and motor nerves from sensory nerves. After Herophilus, many years passed before cadaver dissections again became common practice (Acar et al 2005).

Galen of Pergamon (129–200 A.D.) was a surgeon of gladiators and gained ample experience treating trauma lesions. In addition to the experience he obtained from clinical observation of his patients, Galen performed anatomical studies on baboons. His detailed descriptions of the cerebral meninges, the corpus callosum, the ventricular system, the pineal glands, and the pituitary as well as his primitive classification of cranial nerves owe much to his dissection of these primates. Galen's studies acquired a paradigmatic status that was maintained for 15 centuries. Despite his incontestable contributions to medicine, the infallibility attributed to him led to the perpetuation of anatomical errors, which survived until questioned by the work of Andreas Vesalius (Goodrich and Flamm 2011; Gordon 1993).

During the Middle Ages, while Europe was still in the age of darkness, the Arab and Byzantine cultures were great centers of intellectual production that maintained their hegemony from 750 to 1200 A.D. Arab scholars preserved the studies of their Greek and Roman predecessors and transcribed and systematized the work of Hippocrates, Herophilus, Galen, and Paulus Aegineta, adding their own observations to it.

The Persian Avicenna (the Westernized form of Abu Ali al-Husayn ibn Abdallah ibn Sina) has become known as "the second doctor" (the first being Aristotle). He was born in Afshana, near Bukhara, in the tenth century. An intellectual with many interests, Avicenna was a big name in his day, writing many books on many different subjects: medicine, philosophy, mathematics, astronomy, and poetry (Pereira 2010).

The noteworthy anatomical descriptions contained in his work *Al-Qanun fi al-Tibb* come from his predecessors' studies and his own astute clinical observations, since anatomical dissection was prohibited. His treatise was very influential and was used as a reference work in Western medical schools until the seventeenth century. Avicenna penned one of the earliest clinical descriptions of epilepsy. His treatise contains surprisingly up-to-date anatomical descriptions of the vertebrae. It correlates the form and size of each vertebra with its location and function, demonstrating a biomechanical understanding that was very advanced for the period (Naderi et al. 2003).

Abulcasis (the Westernized form of Abu al-Qasim Al-Zahrawi) was born in Al-Zahra, near Córdoba, Spain, during the period in which Arabs dominated the Iberian Peninsula. He left us an impressive thirty volumes of material on a variety of medical subjects. The thirtieth volume talks about surgery and is rich in illustrations of surgical instruments. Abulcasis defended the use of cauterization and designed a trepan that did not sink into the cranium, preserving the dura mater. He described ping-pong fractures in detail and observed that they were common in children. In addition, he advocated surgical treatment to alleviate headaches by surgically excising part of the temporal artery, which would probably have been related to headaches caused by temporal arteritis. Abulcasis also described various methods of immobilization for treating vertebral lesions (Nayef et al. 1986).

European medicine resurged at long last in the tenth century, with the creation of the Salerno school. The work of Constantine, the African (1020–1087), who studied in Baghdad, shows the marked influence of Arab medicine. In addition to translating medical manuscripts from Arabic into Latin, Constantino reincorporated cadaver dissection into the study of medicine, although his dissections were performed on pigs, rather than humans. Roger of Salerno treated epileptics with trepanation. He examined cranial trauma victims with the help of what we now know as the Valsalva maneuver, asking his patients to exhale so he could observe the flow of blood or fluid through the edges of cranial fractures (Goodrich and Flamm 2011). Theodoric Borgognoni of Serbia (1205–1298) instituted hygienic measures in treating wounds, avoiding dead space, removing necrotic tissue, and applying wine compresses. William of Saliceto (1210–1277) exchanged Arab cauterization for incisions with a chilled blade. Lanfranchi of Milan (1250–1306) created the first medical school in Italy (Mastronardi and Ferrante 2009). Guy de Chauliac (1300–1368) emphasized the importance of shaving the patient's head before surgery; he developed a classification system for cranial wounds with seven subdivisions and advocated using egg white as a hemostatic (Liu et al. 2003a).

During the sixteenth and seventeenth centuries, the practice of neurosurgery continued to be guided by the appearance of lesions rather than by individual patient's symptoms. Much attention was paid to the anatomical characteristics of the lesions, but the study of neurophysiology and the correlation between location and function had not yet been developed. Leonardo da Vinci (1452–1519) made formidable anatomical studies of the central nervous system. He meticulously analyzed the ventricular system with the help of a wax mold he created. Ambroise Paré (1510–1590), neurosurgeon to the House of Medici, defended debridement of

infected lesions by opening the dura mater and cleaning out the blood and pus. The work of Giacomo Berengario of Capri (1470–1530) contained detailed illustrations of surgical instruments and defended the gravitational draining of intracranial abscesses (Goodrich and Flamm 2011; Liu et al. 2003a). Andreas Vesalius (1514–1564) published his *De Humani Corporis Fabrica*, a book that corrected historical errors that had persisted since the time of Galen, thanks to the lack of studies involving cadaver dissection up to that point. Despite the masterfulness of its world-famous illustrations, the *Fabrica*'s style was verbose and labored, making it difficult to read. In general, bibliographies did not tend to cite his text. The book's illustrations are what mainly get mentioned (Goodrich 1985). Thomas Willis (1621–1625), together with Richard Lower (1631–1691), described the "circle of Willis" that now bears his name.

The eighteenth century begot the work of Percivall Pott (1714–1788) and his description of bone lesions caused by tuberculosis. Pott defended trepanation of trauma lesions in order to alleviate symptoms and not just as a treatment for the fracture itself. Benjamin Bell (1749–1806) described the symptoms of compressive lesions caused by cranial trauma and advocated dealing with them quickly.

Worthy of note not just to the history of neurosurgery, but also to the history of surgery in general, was the development of techniques of anesthesia and of asepsis and antisepsis. Over the course of history, different narcotic substances have been used to alleviate pain, such as coca and opium. But it was not until the nineteenth century that pain control took a great leap forward with the introduction of nitrous oxide by Horace Wells in 1844. William Morton, a Boston dentist, spread the use of ether as an anesthetic agent after 1846. Despite ether's popularity, it irritated the mucosae, and it had to be administered through an uncomfortable system of tubes. James Simpson, a professor of obstetrics in Edinburgh, began a series of studies with different substances until he discovered the power of chloroform. This anesthetic is administered using a cloth soaked in the drug. John Snow perfected the method, when he developed a device for inhaling the drug and regularized the quantity of chloroform needed according to each patient's physical characteristics (Hollingham 2009).

In 1847, Vienna's General Hospital hired Ignaz Philipp Semmelweis. His shrewd observations about puerperal fever have not received the recognition they deserve. Semmelweis believed that medical students' hands perpetuated the illness because they were contaminated with remnants of cadaver material from necropsies. Rigorous guidance about handwashing with calcium chlorate led to a steep drop in mortality rates in maternity wards. Unfortunately, despite all the evidence in their favor, Semmelweis' methods were discounted. Semmelweis was the victim of extreme animosity from his colleagues, and recognition of his work came only posthumously (Céline 1998; Hollingham 2009).

Joseph Lister had more success than Semmelweis. Lister followed with interest the work of Louis Pasteur, which was published between 1857 and 1860. Pasteur annihilated microorganisms through boiling. Since Lister could not apply this method to his patients, he killed microorganisms by applying carbolic acid. This substance was first used in 1865 in curatives applied on an exposed fracture and then came to be used in pulverizers in operating rooms (Hollingham 2009).

After the discovery of anesthesia and of aseptic and antiseptic techniques, the next step was recognizing the signs of cerebral localization. Paul Broca (1824–1880) correlated the third circumvolution of the left cerebral hemisphere with the neural mechanism underlying speech after performing a necropsy on a patient with aphasia. John Hughlings Jackson (1835–1911) performed electrophysiological studies on patients with focal convulsive crises, paving the way for the anatomical localization of lesions. In the absence of any imaging methods, anatomical localization of lesions based on their clinical presentation represented a huge advance for neurosurgery (Black and Black 2001; Liu et al. 2003a).

The Pioneers

Rickman Godlee (1859–1925) described the first tumor resected with a topographic diagnostic basis. The patient had a headache and focal convulsive crises that started in the left face and progressed to the arm and leg. The patient's doctor, John Hughes Bennett, who was not a surgeon, made the diagnosis and localization of the tumor and asked for Godlee's support. The patient's convulsions improved, but he died some time later because of infectious complications (Hollingham 2009).

Victor Alexander Haden Horsley (1857–1916), one of the more talented neurosurgeons in history, performed the first successful laminectomy for spinal tumor in this same period. Full of scientific spirit, Horsley developed a compound based on beeswax for hemostasis of the cranium, performed the first carotid ligation to control a cerebral aneurysm, developed a technique to section the posterior root of the trigeminal nerve to treat trigeminal neuralgia, and studied the location of cerebral functions using an electrostimulation. Horsley worked with Robert Henry Clarke, and together, they created the first stereotactic arch, which they used to stimulate and ablate cerebellar nuclei in animals (Tan and Black 2002).

William Macewen (1848–1924) was a staunch defender of antisepsis. He operated with success on many patients, attributing the satisfactory results he obtained to the combination of a proper topographic diagnosis and the use of rigorous asepsis. Macewen modified Lister's technique and placed pulverized carbolic acid on the operative wound. In his time, he was the neurosurgeon who achieved the most success in treating tumors (Black and Black 2001; Goodrich and Flamm 2011; Liu et al. 2003a).

Harvey William Cushing (1869–1939) is considered one of the most important neurosurgeons of all time. Educated at Yale and Harvard, and trained under William Halsted at Johns Hopkins, Cushing raised neurosurgery to a new level. His meticulous technique and preoccupation with asepsis yielded the highest success rates yet. Cushing defended partial tumor resection in cases where total removal might leave sequelae. He had a great faculty for diagnosis and for correctly locating tumors. He was the author of the first pathological classification of gliomas. Cushing described the symptoms of the illness that today bears his name, and he associated it with the presence of basophils in the pituitary gland. He performed his first transsphenoidal surgery in 1909, using the technique

described by Schloffer, a pioneer in this mode of access for surgery on the pituitary. Cushing later developed his own technique via a sublabial incision. He created various instruments for transsphenoidal use (Black and Black 2001; Goodrich and Flamm 2011; Liu et al. 2003a; Maroon 2005).

Walter Dandy (1886–1946), one of Cushing's pupils, developed the technique of pneumoencephalography, thereby inaugurating the era of using imaging to locate lesions. Dandy proved that neuromas could be resected completely. His many contributions to the study of ventricles included work on colloid cysts of the third ventricle and the identification of the choroid plexus as a source of fluid production (Goodrich 2011; Liu et al. 2003a).

Antônio Caetano de Egas Moniz (1874–1955), a Portuguese surgeon, created the angiography in 1927. Together with Dandy's pneumoventriculography, arteriography allowed for a preoperative evaluation of cerebral lesions in terms of their size, location, and vascularization. Egas Moniz also became famous for developing the frontal lobotomy to control psychiatric illnesses. In 1949, he was awarded the Nobel Prize for what was then considered an advance in the treatment of mental illnesses. Nevertheless, after his death, there were demonstrations demanding that the prize be withdrawn (Hollingham 2011; Black and Black 2001).

Among the innovations from this period, we cannot forget to mention Max Nitze's creation of the first modern endoscope in 1879. In 1922, Dandy first used the endoscope to excise the choroid plexus in a patient with hydrocephalus, but without success. The endoscope continued to be used in neurosurgery for some decades, but with low success rates because of the precariousness of the early apparatuses and inadequate lighting. The creation of the ventriculoperitoneal shunts in 1952, a rapid and effective technique to control hydrocephalus, led to the abandonment of surgical endoscopes. Soon, the simple nature of ventriculoperitoneal shunts would be put to the test. Hyperdrainage, infection, and obstruction were frequent complications that reignited interest in endoscopic treatment (Li et al. 2005). With the birth of fiber optics and the development of new technologies, the endoscope is now used not only to treat hydrocephalus but also to resect intraventricular lesions, to access the base of the cranium, in vertebral column surgeries, and as an aid in conventional microsurgeries.

Decades passed between the creation of the first surgical magnifying glass by the ophthalmologist Edwin Theodor Saemisch in 1876 and the popularization of the microscope in the 1960s. Use of the surgical microscope started in otorhinolaryngology; it was introduced in neurosurgery in 1957. Theodore Kurze used the microsurgical technique to remove a facial schwannoma in a 5-year-old patient, having been inspired by a demonstration video made by otorhinolaryngologist William House. In subsequent years, accessories were created to facilitate its use and to make it more comfortable, such as hydraulic chairs, armrests, and the "diploscope," which allowed a second surgeon to assist (Uluç et al. 2009). Use of the microscope has yielded a better understanding of cerebral anatomy and has allowed less and less invasive surgical techniques to be developed, making it possible to observe in detail structures that are not visible to the naked eye. As a result, hemostasis can be performed more safely and precisely, as can tumor

dissection, with less damage to adjacent tissues. The era of "minimally invasive surgery" had thus begun. Mahmut Gazi Yaşargil was a major contributor to the veritable revolution that followed. Vascular and subarachnoid corridors could be identified for the first time, allowing access to structures that were previously considered unreachable. Yaşargil was named surgeon of the century in 1999 at the Congress of Neurological Surgeons in Boston (Black and Black 2001; Uluç et al. 2009).

The Present

The surgical microscope led to a better understanding of intraoperative anatomy. Other milestones included the introduction of the Malis bipolar forceps, the ultrasonic aspirator, and, more recently, the ultrasound bone cutter. The rise of computed tomography in the 1970s and of imaging magnetic resonance almost a decade later transformed completely the preoperative study of cerebral lesions. For the first time, their morphology could be visualized, and even their functional characteristics could be assessed. Tomography with the administration of a contrast dye can identify breaks in the blood–brain barrier and indicate tumor vascularization grade. Magnetic resonance images have allowed clinicians to estimate the water content of tumors, stage of malignancy, and blood perfusion. Localization systems guided by images have been perfected with the creation of the first arches for tomography-guided stereotaxy and, later, with neuronavigational devices which, in turn, show the location of a surgical instrument in relation to the operative field without having to place a rigid fixation arch on the patient's cranium (Tatagiba et al. 2012). Intraoperative information is correlated with preoperative data, acquired by computed tomography or imaging magnetic resonance, resulting in an image on the monitor that shows, in real time, the surgical instrument's position in relation to the brain or spinal cord (Tatagiba et al. 2012).

In recent years, neurosurgery has made great leaps forward by taking advantage of new and rapidly developing technologies. Compared to the period before the application of these technologies, operations are now being conducted more safely, with less hospitalization time and less discomfort to patients, and with reduced complication rates.

In addition, the surgical environment has changed to accommodate new equipment, taking full advantage of all available space. These changes have borne the concept of integrated operating rooms, which link imaging equipment, such as high-field intraoperative magnetic resonance, to neuronavigational systems. This technology, now widely available, allows brain tumors to be resected more completely (Liu et al. 2003; Roder et al 2012).

Thanks to the perfection of ergonomics, surgeons operate in greater comfort. And now there is hope that, in the near future, we will be able to replace bulky microscopic surgery with a compact and integrated video system, a concept known as video microsurgery (Ebner et al. 2011). In the field of endoscopy, new guided and multidirectional endoscopic prototypes are under development (Ebner et al. 2012a),

as are techniques for perforation and hemostasis assisted by 2-micron fiber lasers for intracranial endoscopic procedures (Ebner et al. 2012b, c). More and more reliable virtual reality devices permit safer planning of surgeries, making an enormous contribution to the training of medical residents, who can now practice many times on simulators before operating on a patient (Elder et al. 2008).

The Future

Robotic assimilation of the brain-computer interface and of nanotechnologies and advances in neuromodulation and stem cells studies are some of the main thrusts for future development.

In the field of robotics, spinal surgery guided by robots is already well established (Devito et al. 2010). Among the current models, *SpineAssist* merits mention; it is used in operations to implant percutaneous pedicle screws for lumbar fusion, significantly improving performance compared to the conventional freehand technique (Devito et al. 2010). Also worthy of mention is the *da Vinci* robotic-assisted laparoscopic anterior lumbar stand-alone interbody fusion procedure via a transperitoneal approach (Beutler et al. 2013). And still in development are assistants for mastoidectomy, a procedure of great precision that requires considerable physical force (Plinkert et al. 2001; Danilchenko et al. 2011).

The period of the last 15 years has brought very promising developments in honing of the brain-computer interface. Science fiction films raised the idea of using thought to move machines (Leuthardt et al. 2006). Today, there are some experimental studies on nonhuman primates and humans in which electrodes are implanted on the cerebral cortex; these electrodes recognize cortical electrical activity and translate signals into actions, such as moving a robotic arm or a suit (exoskeleton) (Leuthardt et al. 2006; Lebedev et al. 2011). In years to come, neurosurgeons will need to remain attentive to brain-computer interface technologies, as well as to the implementation of implantation surgery (Leuthardt et al. 2006). This new era gives the neurosurgeon the opportunity to be active not only in stemming neural tissue damage but also in rehabilitating and recuperating lost functions (Leuthardt et al. 2006).

In the field of nanotechnology, the development of devices with even smaller dimensions will lead to progressively less invasive procedures. Microelectromechanical and nanoelectromechanical systems can act as sensors to identify specific substances, such as markers for tumors or bacterial infections, with infinite possibilities. Nanoparticles offer a means of administering medicine with precision. We will develop systems of biocompatibility to avoid potential immunological reactions to new prostheses (Elder et al. 2008). Finally, as we elucidate the behavior of stem cells, we will be able to harness the way they mature, proliferate, and differentiate to enhance recovery from ischemic brain lesions and degenerative diseases, among other conditions (Elder et al. 2008).

Thus, the future looks promising. Neurosurgery is a constantly evolving field, and it requires practitioners to continually study and extend themselves to absorb

new technologies. We have reached the present state through the hard work of our predecessors. These pioneers opened up the previously unknown territories of anatomy and physiology and discovered the laws of physics and chemistry, guided by their love of knowledge and their humanity. Never before in the history of neurosurgery has science progressed as fast as it has in our era. We must, nonetheless, give a respectful nod to our predecessors, who paved the way for us.

Awake Craniotomies: Burden or Benefit for the Patient?

61

G. C. Feigl, R. Luerding, and M. Milian

Contents

Abstract

An awake craniotomy with intraoperative neuropsychological monitoring and brain mapping is still the gold standard for resections of tumors in or near eloquent areas of the brain. Since it has been shown by several authors that an awake craniotomy is the only way to reliably preserve speech function during tumor resections, the benefits for patients undergoing such a procedure are obvious. However, an awake craniotomy represents an exceptionally stressful situation for a patient, which could possibly lead, similar to an awareness experience during surgery, to long-term psychological sequelae. Therefore the question has to be

raised if it is justified and ethical to submit patients already under a high amount of stress due to the uncertain future and with existential fears to even more strain by operating them awake. However, when balancing the burdens of an awake craniotomy for a patient with the benefits of such a procedure, it becomes obvious that an awake craniotomy and here especially the awake–awake (= continuous awake craniotomy - CAC) method offer the best thinkable balance between an optimal tumor resection and the best possible preservation of cognitive functions. Considering that persistent deficits of essential language and motor function have a much worse effect on a patient's quality of life than rare but treatable posttraumatic stress disorder symptoms, it seems unethical not to offer an awake craniotomy to patients when the location of the tumor justifies such an operation.

Introduction

The first and most important step in any treatment of primary malignant brain tumors is a gross total resection (GTR) (Filippini et al. 2008; Gorlia et al. 2008; Mineo et al. 2007). This however is not always possible because primary brain tumors in most cases infiltrate the surrounding brain tissue. In 1928 Walter Dandy went to an extreme and used hemispherectomies in an attempt to cure patients with malignant primary brain tumors. Yet despite the massive neurological deficits caused by the surgical procedure, these patients suffered recurrences in the opposite hemisphere of the brain. At that time survival of the patient at any prices was the main focus. Even though this seems unethical with today's understanding of neuroethics, the intention of neurosurgeons was the same then as it is today which is to offer the best possible treatment to the patient and save his/her life. The basic idea of Dany to try to remove as much tumor as possible in order to increase the survival of patients with primary brain tumors was correct and has been confirmed in several studies that show that a GTR plays a central part in overall survival of these patients (Berger et al. 1989; Buckner 2003; Stummer et al. 2008; Tait et al. 2007). Nowadays, however, the focus is wider of course when it comes to choosing the best treatment for a patient and also takes the quality of life and preservation of function of a patient into consideration. Nevertheless, the diagnosis of a brain tumor is still a very distressful and threatening situation for a patient. In cases where the tumor is located adjacent to or in an eloquent brain area (i.e., language or motor cortex), a precise intraoperative localization of functional areas is absolutely essential in order to avoid causing deficits during microsurgical tumor removal in eloquent areas of the brain. Even though there are well-known anatomical landmarks to localize functional areas on the cortical surface, they are no longer applicable if functional areas and cerebral tracts are displaced by a space-occupying lesion. Therefore awake craniotomies with intraoperative neuropsychological monitoring and cortical mapping are still the gold standard for tumor resections in or near eloquent cortical areas (Berger et al. 1989; Berger and Ojemann 1992; Duffau 2005; Duffau et al. 2003).

However, an awake craniotomy represents an exceptionally stressful situation for a patient, which could possibly lead, similar to an awareness experience during

surgery, to long-term psychological sequelae (Lennmarken et al. 2002; Leslie and Davidson 2010). However, to this date possible long-term psychological consequences of an awake surgery for neither of the two available protocols (asleep–awake–asleep/awake–awake = continuous awake craniotomy - CAC) are really known. Also, do the benefits for the patients outweigh the burden and stress they are put through when undergoing an awake craniotomy? It has to be considered that postoperative posttraumatic stress disorder (PTSD) symptoms could occur in these neurosurgical patients and certain pretrauma and peritrauma environment factors (e.g., age, gender, pulse rate during mapping, surgery duration) might be associated with psychological symptoms after an awake craniotomy. Furthermore the effect of these symptoms on postsurgical health-related quality of life (HRQoL) has to be taken into consideration when planning an awake surgery for a brain tumor patient. Yet very few studies are available that deal with patients' perceptions of awake craniotomy. Wahab et al. studied the patients' satisfaction with the awake craniotomy procedure and reported that 24 % of the patients experienced some discomfort during surgery, some of which was related to the intraoperative positioning of the patient, and 56 % reported no postoperative pain (Wahab et al. 2011). Whittle et al. reported significant intraoperative pain in 20 % of the patients investigated, and strong anxiety was found in 13 % of the patients (Whittle et al. 2005). In a further study patients were interviewed 1–2 weeks postsurgery (Khu et al. 2010). The results reflected positively on the patients' awake surgery experience, but there were some areas that require improvement, specifically perioperative pain control and postoperative care.

Therefore the question could be raised if it is justified and ethical to submit patients already under a high amount of stress due to the uncertain future and with existential fears to even more strain by operating them awake. For most people it is stressful enough to only think of a dental treatment, but what about an operation on the brain in a conscious state? More so then in a dentist's chair, the patient exposes himself/herself in an awake craniotomy to a situation he/she cannot control which raises fears.

Protocols for Awake Craniotomies

Indications for Awake Craniotomies

The main indications for an awake craniotomy are primary brain tumors in eloquent areas of the brain influencing the speech function. This means any lesion near the two speech centers, Broca and Wernicke and their connecting fiber bundle, the arcuate fascicle, represents an indication for an awake craniotomy. Also patients with Parkinson's disease are generally operated awake so that the correct placement of the electrodes can be tested intraoperatively. The focus of this chapter however is set on awake craniotomies for patients with primary brain tumors. Lesions near the central sulcus no longer represent an indication for an awake craniotomy. The reason is that available electrophysiological monitoring machines allow a very refined localization of the motor area and fiber tracts with cortical and subcortical stimulation on patients even under deep sedation.

The Asleep–Awake–Asleep Protocol

The standard anesthesiological protocol for an awake craniotomy with cortical stimulation and language mapping is the asleep–awake–asleep method (Huncke et al. 1998; Mack et al. 2004; Sarang and Dinsmore 2003; Schulz et al. 2006) named after the three phases the patient is in during the procedure. The patient is "asleep" during the craniotomy, and then sedation is interrupted so the patient is "awake" for cortical stimulation and language testing. After testing is completed, sedation is continued and the patient is again "asleep" for the closure of the skull and skin. Even though this protocol seems to be optimal for patients undergoing awake craniotomies since the patient is left asleep during opening and closure of the skull and is awoken only for language testing, it carries potential risks with respiratory complications and hemodynamic dysregulation being most commonly reported (Danks et al. 2000; Huncke et al. 1998; Keifer et al. 2005; Mack et al. 2004; Manninen et al. 2006; Sarang and Dinsmore 2003; See et al. 2007; Sinha et al. 2007; Skucas and Artru 2006). Furthermore, using the asleep–awake–asleep protocol, patients are always more or less hangover from sedation, leaving them bradyphrenic during neuropsychological testing. This potentially falsifies functional test results creating uncertainty with regard to determining the exact borders of functional areas. Since testing patients intraoperatively is the central part of these procedures, any factors creating an uncertainty during testing should be avoided.

The Awake–Awake Protocol (Continuous Awake Craniotomy/CAC)

In an effort to eliminate potential risks for the patient during awake craniotomies and in order to improve reliability of intraoperative test results which have a direct influence on the surgical outcome of awake craniotomies, the awake–awake protocol has been developed. This protocol is called awake-awake / CAC because using this protocol the patients are not deeply sedated during the procedure and whenever possible no sedatives are used at all. Patients undergoing this procedure receive an intravenous line as well as arterial cannulation (radial artery) for continuous arterial blood pressure monitoring and blood gas analyses. Noninvasive monitoring of vital functions included electrocardiography, a blood pressure cuff, pulsoximetry, and a nasal oxygen mask. Respiratory rate and end-tidal carbon dioxide were measured using a nasal prongs port with capnometry (CO_2 port). Due to the long duration of these procedures, patients receive also a urinary catheter. No airway instrumentation is required but is generally kept within reach of the anesthesiologist in case that a non-self-limiting seizure causing a drop in oxygen saturation (<90 %) occurs.

At least 20 min before the Mayfield head clamp was applied using 0.75 % ropivacaine supplemented with Adrenalin (diluted 1/200,000), scalp nerve blocks (SNB) are placed through a 23 gauge needle (Nguyen et al. 2001a). In order to reduce the psychological stress for the patient in this situation, it is important that a member of the surgical team, either the neuropsychologist or the anesthesiologist, keeps close contact to the patient. This includes not only standing near the patient

but holding his/her hand and talking to him/her and thereby reducing his/her fear because his/her focus is no longer on the surrounding but on the person he/she is talking to. This can be described as a close and individual intraoperative patient guidance and pacing which has been shown to increase the comfort and significantly reduce the stress of patients in such a situation.

Brain Mapping and Neuropsychological Evaluation

Independent of the protocol used, neuropsychological testing and extensive brain mapping with direct cortical stimulation are important to locate functional areas shown on the fMRI scans and confirm their location before the tumor resection is started. Since gliomas generally show an invasive pattern of growths, it is essential to detect functional borders and fiber tracts without compromising the radicality of the resection by stopping the resection too soon. If the tumor is located in or near a functional speech area, neuropsychological testing in combination with subcortical stimulation during the resection helps to detect functional borders and fiber tracts before permanent neurological deficits are caused. Brain mapping, however, can trigger a generalized seizure which is one of the distressful situations for the patient in such a situation. However commonly these types of seizures can be controlled by irrigation of the brain with cold ringer solution (Nguyen et al. 2001a, b; Sartorius and Berger 1998).

For the neuropsychological evaluation during brain mapping and surgery, the patients usually are asked to perform picture naming to identify language areas which are known to be inhibited by stimulation.

Differences in the Anesthesiological Protocols

Management of the airways is a critical part of the standard asleep-awake-asleep protocol with the danger of aspiration due to nausea and vomiting in the phase when the patient wakes up during the surgery for language testing. Various techniques of the airway management are described in literature ranging from leaving the patient breathing spontaneously (Keifer et al. 2005) and securing the airway transnasally with a Magill tube (Schulz et al. 2006) or with a laryngeal mask (Sarang and Dinsmore 2003). In some cases patients are even ventilated using a laryngeal mask (Sarang and Dinsmore 2003) or intubated for the asleep part of the surgery (Huncke et al. 1998). In some centers skull nerve blocks are used for regional pain management during opening of the skin and the craniotomy (Schulz et al. 2006; Sinha et al. 2007). All these manipulations on the patient who is in a "half-awake" state increase his/her feeling of discomfort and helplessness and therefore create stress. A review of recent literature (Table 61.1) reveals that the asleep–awake–asleep protocol is most commonly used during awake craniotomies. These methods have their advantages but also limitations and, more importantly, potential risks are usually not discussed in detail since many publications focus primarily on functional

Table 61.1 A summary of studies on awake craniotomies and reported rates of complication

Author	Number of treated patients	Anesthesiological protocol used	Problems during the wake-up phase or during neuropsychological testing	Extend of tumor resection	Intraoperative seizures	Respiratory complications	Hemodynamic dysregulation	Brain swelling "tight brain"	Other intraoperative complications	New neurological deficits after surgery

and surgical results (Table 61.1). Many authors who do discuss intraoperative complications during awake craniotomies report respiratory complications in up to 37 %, circulatory dysregulation in up to 22 %, brain edema in up to 14 %, and uncooperative or agitated patients in up to 20 % (Danks et al. 2000; Keifer et al. 2005; Mack et al. 2004; Manninen et al. 2006; Picht et al. 2006; See et al. 2007; Sinha et al. 2007). Severe complications with patients waking up uncoordinated and in some cases even pulling themselves out of the Mayfield head clamp inflicting severe injuries on themselves have also been reported. All of these complications are related to sedative agents used during the "asleep" phase of awake craniotomies. Furthermore, these substances have a direct influence on neuropsychological test results; however, intraoperative testing is the prime reason to perform an awake craniotomy in the first place.

The awake–awake / CAC protocol could be safer for patients than other methods used for awake craniotomies. Since there is no drug-related change in the level of consciousness during the entire procedure, it is not surprising that patients are cardiopulmonary stable and that monitoring is generally uneventful for the anesthesiologist. It could be objected that opioids also have a sedative effect. However, the sedative effect of opioids in dosages required for the awake–awake / CAC protocol (approximately 0.1–0.3 mg/h and over a mean period of only 60 min) is by far weaker and therefore not comparable to the sedative effects of barbiturates or other general anesthetics. Also, it is not widely known that several studies specifically analyzing and evaluating the effects of drugs on human memory (Ghoneim 2004a, b) have shown that general anesthetics do impair short-term memory which is highly relevant during intraoperative language and memory testing, while opioids do not show such an effect (Ghoneim 2004b).

Burdens and Benefits of Awake Craniotomies for the Patient

Definition Posttraumatic Stress Disorder (PTSD) and PTSD Symptoms

Since it has been shown by several authors (Berger et al. 1989; Berger and Ojemann 1992; Duffau 2005; Duffau et al. 2003, 2005) that an awake craniotomy is the only way to reliably preserve speech function during tumor resections in or near the speech centers, the benefits for patients undergoing such a procedure are obvious. However, in order to analyze the possible psychological sequelae and their burden on the patient, possible psychological symptoms have to be defined in order to identify them correctly. Based on this information it is then somewhat easier to decide in each individual case whether or not it is ethical to submit a patient to the stress of an awake craniotomy.

According to the definition of the DSM-IV (American Psychiatric Association 1994), PTSD is the development of three main types of characteristic symptoms after an extreme traumatic stress experience (e.g., violation, kidnapping, or the diagnosis of a life-threatening disease). The person's response to the trauma must

involve intense fear, helplessness, or horror (criterion A). The three clusters of symptoms include (i) persistent reexperiencing of the traumatic event (criterion B), (ii) persistent avoidance of stimuli associated with the trauma and numbing of general responsiveness (criterion C), and (iii) persistent symptoms of increased arousal (criterion D). The symptoms must be present for more than 1 month (criterion E) and must cause sufficient distress that leads to occupational or social impairment (criterion F). In the study of Milian et al. (2013) patients were considered to have PTSD symptoms if they reported both having a traumatic event (criterion A) and having at least one of the symptoms from any of the three core clusters (criteria B, C, D). In a previous study it has been shown that positive symptoms for both criterion A and criterion B correctly identified 97 % of PTSD cases. If only single items of the respective criteria (A, B, C, D, or F) are stated positively, patients were considered to show postoperative psychological symptoms; however, these do not fulfill the criteria for a clinically relevant PTSD or PTSD symptoms.

Balancing Burdens and Benefits of an Awake Craniotomy

The risk of affecting the state of arousal of patients during an awake surgery has not yet been quantified in many studies. Since the anesthetist closely observes and protocols the patients' vital parameters such as heart rate, blood pressure, and breathing frequency during an awake craniotomy, he/she has quite sensitive parameters for estimating a change of arousal connected to the awake surgery setting and therefore the possibility to immediately react to it. Therefore the anesthetist has all diagnostic and treatment tools for detecting early signs of stress symptoms and to treat changes of arousal before the level reaches the level of real stress symptoms.

The risk of postoperative psychological sequelae in the sense of posttraumatic stress disorder (PTSD) and the patients' perceptions of awake surgery have so far only been described in very few studies (Milian et al. 2013; Whittle et al. 2005; Khu et al. 2010). Around 12 % of the patients showed PTSD symptoms postoperatively. In one case the symptoms were chronic; in the other case the symptoms resolved within 3 months. However, it is worth mentioning, that no patient that underwent an awake craniotomy fulfilled the criteria for a clinically relevant PTSD after the awake surgery. Physiological parameters such as pulse and blood pressure during the awake craniotomy or the duration of surgery were no predictors for the development of postsurgical psychological symptoms after the procedure. Although PTSD symptoms are rare, isolated psychological symptoms after awake surgery in form of either reexperiencing the event, avoiding of stimuli associated with the event, or symptoms of increased arousal occur to a considerable degree and have a clear negative impact on quality of life (Milian et al. 2013). However, these effects are treatable with a high rate of full recovery (Peris et al. 2011). The rate of recovery of stress symptoms after a suitable therapy exceeds significantly the

effects of neurocognitive training and physiotherapy after postoperative impairment of language and motor functions.

The preservation of language and motor functions is highly significant for the quality of life of a patient. Currently there is no better method available than the awake craniotomy to evaluate speech function during tumor resection. Especially the awake–awake / CAC method offers the best options to test the patient without the influence of sedatives that might falsify intraoperative test results. Furthermore, this protocol significantly reduces the risk for the patient to suffer sedation-related complications such as respiratory complications and hemodynamic dysregulation. Also, potential risks during the intraoperative wake-up phase are avoided since the patient is awake the entire time and intraoperative neuropsychological test results become more reliable. Since the neurosurgeon has to perform the resection to the limit of representations of essential cognitive functions with a maximum of precision, the control of the resection size only by artificial measures such as the fMRI and DTI coordinates bears the incalculable risk of an unjustified confidence in these artificial measures. In awareness of this risk, the neurosurgeon is in most cases far too conservative in estimating the limits of resection (Duffau et al. 2005). This results as a consequence in a smaller tumor volume reduction in comparison to awake resections and therefore in a significantly shorter survival of the patient.

The Protective Effect of Preparing the Patient for an Awake Surgery

Patient selection is a central part in the preparation of an awake craniotomy. The fact that the patient has to play an active role during the entire procedure, especially when using the awake–awake / CAC protocol, might seem frightening to many patients. Besides personality also the ethnic background potentially plays a role in the willingness of a patient to undergo such a surgery. Therefore the neurosurgeon, the anesthesiologist, and the neuropsychologist have to separately talk to the patient and then compare their impressions of the patient and decide whether or not a patient is suitable to undergo an awake surgery. While it is important to openly discuss with the patient the things that can happen during an awake craniotomy, trying to take the patient's fear, it should never be attempted to convince a patient if he/she is not willing or feels not capable of putting himself thru this stressful situation. Patients who are anxious or have a decreased level of motivation generally will not perform well intraoperatively. Therefore, patients who are scheduled for an awake craniotomy have to undergo a thorough preoperative preparation before surgery and should be informed extensively about possible anxiety, pain, noise, seizures, or the inability to name things or speak during language mapping.

During the operation (from skin incision to suture) besides the anesthesiologist, also a neuropsychologist should be present and continuously communicate with the patient. Before performing the craniotomy, the neuropsychologist or the anesthesiologist should try to distract the patient from the stressful situation by trying to associate the noises and phenomenon experienced during the trepanation to

Fig. 61.1 The anesthesiologist keeps close contact to the patient who is operated awake with the awake–awake protocol, placing his/her hand on the patient's shoulder during the trepanation performed by the neurosurgeon in the background of the picture. The anesthesiologist tries to distract the patient from the noise of the drill by trying to associate the phenomenon experienced during the trepanation to a different and positive situation outside the operating room with positive suggestions like "Imagine your are on vacation and your plane is just landing. . .." To keep eye contact between the anesthesiologist and the neurosurgeon, a clear drape is used

a different and positive situation outside the operating room with suggestions like "Imagine your are on vacation and your plane is just landing" (Fig. 61.1). During the surgical procedure, stress for the patient can easily be reduced by engaging him/her into a conversation which at the same time serves as a monitoring of the patient's language function. While it has been described that patients who experienced an awareness during surgery developed PTSD (Lennmarken et al. 2002; Leslie and Davidson 2010), patients who underwent awake craniotomy did not present with similar late psychological sequelae. Therefore, while an unexpected and unprepared awareness during surgery leads to traumatic effects, an adequate preparation seems to have a positive and protective effect for the patient.

Conclusion

Balancing the burdens of an awake craniotomy for a patient against the benefits of such a procedure, it becomes obvious that an awake craniotomy and here especially the awake–awake / CAC method offer the best thinkable balance between an optimal tumor resection and the best possible preservation of cognitive functions. Considering that persistent deficits of essential language and motor function have a much worse effect on a patient's quality of life than rare but treatable posttraumatic stress disorder symptoms, it seems unethical not to offer an awake craniotomy to patients when the location of the tumor justifies such an operation.

Abstract

One percent of the global population, children as well as adults, are affected by epilepsy. In about one third of patients, seizures cannot be adequately controlled by antiepileptic medication. A significant proportion of these patients, especially of those with focal epilepsy, may benefit from epilepsy surgery. Given the patients' reduced quality of life and the high social and economical burden of uncontrolled seizures, early consideration of epilepsy surgery is recommended. Curative epilepsy surgery procedures aim at abolishing the seizures by removing or disconnecting the area generating the seizures, without causing an unacceptable functional deficit. Palliative procedures aim at reducing the frequency and/or severity of seizures in patients who cannot be rendered seizure-free. Overall, there is a 40–80 % chance of postoperative seizure freedom, with a low risk of perioperative morbidity if the procedure is performed by an experienced

neurosurgeon. In adults with temporal lobe epilepsy, two randomized controlled trials have provided evidence of the superiority of surgery over medical treatment alone.

To determine whether a patient is a candidate for epilepsy surgery and which procedure is deemed to produce the most benefit, a comprehensive evaluation needs to be performed, taking into account the type of epilepsy and its expected evolution, the individual aims and the psychosocial situation of the patient, the presence or absence of a resectable structural lesion, and the risks associated with the surgery. This chapter examines the ethical challenges related to epilepsy surgery with respect to patient selection, quality of life, and informed consent.

Introduction

Epilepsy is a chronic neurological disease affecting about 0.5–1 % of the general population, children and adults (Hauser et al. 1993). It is characterized by recurrent, unprovoked seizures caused by an inappropriate paroxysmal electrical discharge in the brain. In the majority of patients, the seizures have a focal or regional onset, but most seizures produce activation of a more or less extensive network of cortical and subcortical brain structures. According to the brain areas involved, seizures may manifest as a disturbance of perception, consciousness, or behavior, the maximum expression being a generalized convulsion. About one third of patients with epilepsy are considered drug resistant, meaning that they continue to have seizures despite appropriate pharmacotherapy, or the medication causes unacceptable side effects. It has been shown that the chance of becoming seizure-free with medical therapy alone declines to less than 20 % when a patient has failed adequate trials of 2–3 standard antiepileptic drugs (Kwan and Brodie 2000).

In addition to the impairment of quality of life and social functioning caused by recurrent, unpredictable seizures, uncontrolled epilepsy is associated with significant comorbidities. Mood disorders such as depression or anxiety are four times more frequent than in the general population (LaFrance et al. 2008), and patients often have cognitive deficits due to the underlying disease, medication side effects, or the effect of the seizures themselves. Children with frequent seizures from an early age are impaired in their development (Cross et al. 2006). As they get older, they face increasing psychosocial problems due to the embarrassment and stigma caused by seizures occurring in public, restricted personal autonomy and vocational choices, and the inability to drive motor vehicles. In addition, there is a significantly higher risk of mortality due to injury and sudden death. A recent epidemiological study (Sillanpää and Shinnar 2010) has identified a threefold increase in mortality compared to the general population over an observational period of 40 years.

A substantial proportion of patients with drug-resistant epilepsy, especially of those with focal-onset seizures, may benefit from surgical treatment. In general, two types of surgeries can be distinguished: curative and palliative procedures. Curative procedures aim at achieving seizure freedom by resection or disconnection of the area capable of generating seizures, the so-called epileptogenic zone, without

causing an unacceptable functional deficit. Procedures can be standardized or customized and range from circumscribed cortical excisions, to partial or total resection of an entire lobe of the brain (e.g., anterior temporal lobectomy), to multilobar resections or even hemispherectomy, i.e., removal or functional disconnection of one hemisphere, in patients with severe unihemispheric epilepsy. The amount of brain to be resected or disconnected depends on the nature and localization of the underlying pathology and the presumed extent of the epileptogenic zone. The most frequent pathologies causing drug-resistant seizures amenable to resective epilepsy surgery are low-grade tumors, mesial temporal sclerosis, and malformations of cortical development. In adults, up to 75 % of resections for drug-resistant epilepsy involve the antero-mesial temporal lobe. In children, extra-temporal and multilobar resections are more frequent. Overall, in appropriately selected patients, there is a 40–80 % chance of postoperative seizure freedom, varying according to localization and pathology (Tellez-Zenteno et al. 2005; Spencer and Huh 2008), with a low risk of perioperative morbidity if the surgery is performed by an experienced neurosurgeon. In adults with temporal lobe epilepsy, two randomized controlled trials have provided evidence of the superiority of surgery over medical treatment alone in terms of seizure freedom and quality of life (Wiebe et al. 2001; Engel et al. 2012).

Palliative procedures aim at reducing the frequency and/or severity of seizures in patients who are not considered candidates for curative surgery. This refers to patients with multifocal or bi-hemispheric epilepsies, as well as patients in whom the seizure-onset zone involves eloquent areas. Procedures include the partial resection of the epileptogenic zone in order to spare eloquent cortex, disconnection of cortical areas or white matter tracts to prevent seizure spread such as corpus callosotomy or multiple subpial transections, and electrical stimulation of different targets in the central or peripheral nervous system through an implanted device, with the intent of reducing the excitability of networks thought to play a role in the generation and propagation of seizures.

What distinguishes epilepsy surgery from other neurosurgical interventions to warrant specific ethical considerations? First, it is an elective procedure, and it is (in most cases) irreversible. Therefore, risks and benefits have to be weighed much more carefully than in the case of an emergency intervention undertaken to avert immediate harm. Second, it is a surgical intervention performed with the intent of curing or at least ameliorating a *functional* disorder of the brain. Even though it often entails resection of structural abnormalities, seizures are an electrical phenomenon and the "epileptogenic zone" is an elusive concept. In addition, seizures are generated in potentially functional cortex, meaning that removal of the epileptogenic zone may involve trade-offs in terms of neurological function. Third, many patients who may benefit from epilepsy surgery are legally underage and/or cognitively impaired, which creates additional challenges when obtaining informed consent.

While an in-depth discussion of different ethical theories is beyond the scope of this chapter, the general ethical principles guiding medical professional conduct are considered to be respect for (patient) autonomy, non-maleficence, beneficence, and

justice, with the ultimate aim of achieving the highest good for the patient (Beauchamp and Childress 2009). In the following paragraphs, ethical issues arising in the different stages of the decision-making process will be highlighted.

Candidacy for Epilepsy Surgery

Who is a candidate for epilepsy surgery and how should candidacy be determined? Professional societies concur that every patient with drug-resistant, disabling seizures is a *potential* surgical candidate (Engel et al. 2003; Cross et al. 2006). However, in order to determine whether an individual patient is an *actual* candidate, a comprehensive evaluation needs to be performed, taking into account the type of epilepsy and its expected evolution, the individual aims and the psychosocial situation of the patient, the presence or absence of a resectable structural lesion, and the risks associated with the surgery. This evaluation requires specific expertise, since many epilepsy surgery procedures are not part of standard neurosurgical practice. Given that epilepsy surgery is an elective procedure, timing also becomes an issue. Therefore, while it is the responsibility of the local primary care physicians and specialists (family practitioners, pediatricians, or neurologists) to *initiate* the evaluation for surgical candidacy, the evaluation itself and the final decision whether the patient is likely to benefit from surgical treatment and which type of surgery to recommend should be undertaken in a specialized center with the necessary resources.

Unfortunately, considerable inequity still exists in terms of access to specialized epilepsy centers, with the result that many patients who could benefit from epilepsy surgery are not referred for evaluation. This can often be attributed to informational deficits but in many parts of the world simply to nonexistence or uneven distribution of adequate resources.

The Presurgical Evaluation

The primary purpose of the presurgical evaluation is to identify the so-called "epileptogenic zone," defined as the *minimal* area of cortex that must be resected in order to achieve seizure freedom (Lüders et al. 2006). By definition this includes the seizure-onset zone but also other areas *potentially* able to generate seizures once the current seizure-onset zone has been resected. Therefore, it can be known only *after* the surgery (= when the patient is seizure-free) whether the epileptogenic zone has been inactivated. Since there is no single diagnostic test that allows to determine its extent with certainty, a number of different examinations have to be performed that, taken together, provide an approximation of the epileptogenic zone. In addition to thorough history taking, this includes high-resolution MRI to identify potentially epileptogenic lesions, integrated video-EEG monitoring to delineate the seizure-onset zone, and interictal electrical abnormalities, as well as a neurological examination supplemented by neuropsychological tests and eventually by

functional imaging, to identify functional deficits and indicate eloquent areas that have to be spared during surgery. If the information obtained through noninvasive investigations is not sufficient to make a final decision, or the presumed seizure-onset zone is close to relevant eloquent areas such as language or motor function, invasive video-EEG recordings with implanted subdural or depth electrodes may be necessary to delineate the area to be resected. In this case, as for all invasive procedures, the expected benefit in terms of informational gain has to be weighed carefully against the risk of complications.

Finally, a synthesis of the information obtained has to be created. The more results converge to indicate one circumscribed area, the better the estimate of the epileptogenic zone and the higher the chance of postoperative seizure freedom. If the epileptogenic zone cannot be identified with sufficient certainty or is deemed too extensive or too close to eloquent areas to be removed completely, a cure of the patient's epilepsy becomes unlikely. In this case, a palliative approach may be considered.

The Question of Quality of Life

The goal of epilepsy surgery is to abolish or ameliorate the patients' seizures, but the underlying intent is to improve their quality of life. Beauchamp and Childress (2009) note that it is impossible to determine what will benefit a patient without presupposing some quality-of-life standard and some conception of the life the patient will live after the (surgical) intervention. Therefore, the first question that arises is how to define quality of life and how to measure it. For research purposes, a number of standardized instruments have been developed to evaluate quality of life in general and specific for epilepsy, assessing the patient's subjective perception of the impact of disease and treatment on multiple dimensions of health status, such as physical, psychological, and social functioning, based on the patient's report (Cramer et al. 2002).

Published outcome research has shown that, on average, quality of life as assessed with these tools does indeed improve significantly after epilepsy surgery, in children as well as in adults (Spencer et al. 2007; Seiam et al. 2011; Elliott et al. 2012; Engel et al. 2012; Zupanc et al. 2010). Not surprisingly, the most important *postoperative* determinant of quality of life has been found to be seizure freedom. There is only a limited improvement for patients who are not seizure-free. In this regard it has to be remembered that even for surgical procedures with curative intent, the statistical likelihood of seizure freedom is not 100 % but can be considerably lower according to the accurateness of localization of the epileptogenic zone and the underlying pathology. For palliative procedures, the likelihood of seizure freedom is by definition close to 0 %. In the end, only a minority of patients regret having undergone epilepsy surgery, even if they do not become seizure-free (Macrodimitris et al. 2011). However, while common intuition suggests that any improvement is worth obtaining, and desperate patients as well as healthcare professionals eager to help may be inclined to grasp every straw,

a critical assessment of how much a mere reduction in frequency and/or severity of seizures will actually impact quality of life is paramount when determining the potential benefit for patients with a low chance of seizure freedom.

Outcome research has also shown that seizures, while they tend to dominate patients' preoccupations, are not the only determinant of postoperative quality of life. Not surprisingly, given the high prevalence of neuropsychological impairment and mood disorders in patients with refractory epilepsy, it has been found that the most important *preoperative* determinant is psychological status. This should not lead to the conclusion that patients with psychiatric comorbidities cannot benefit from surgery, and excluding them a priori would go counter the ethical principle of justice, but it has to be kept in mind that these patients require a thorough psychiatric evaluation and that psychological assistance will have to extend into the postoperative period, lest the expected benefit in terms of improvement of quality of life may not manifest.

Last but not least, it should not be forgotten that it can be very difficult to use standardized tools to assess quality of life in patients with reduced mental capabilities who are not able to fill in questionnaires or report on what makes life worth living. For these patients, more "practical" indicators of quality of life, such as injuries through falls or the need to wear a helmet, may need to be applied.

Towards a Patient-Centered Outcome

Meta-analyses of outcome data and guidelines issued by professional associations provide valuable information for the physician seeking to determine the *general* chances and risks of different therapeutic approaches. However, the average patient may be quite different from the individual patient being counseled. While some common determinants exist, quality of life is personal and patients have their own idiosyncratic aims for surgery. The fact that epilepsy surgery is an elective procedure (meaning that the patient voluntarily chooses it with the aim of improving the patient's condition) makes patient satisfaction the most important meter of treatment success. Standardized quality-of-life questionnaires should therefore be supplemented by an in-depth interview with the patient and/or caregivers, in order to really understand the motivation of the patient and his or her social environment (Taylor et al. 2001). The desire to be seizure-free appears quite straightforward, but there are secondary goals such as independence, driving motor vehicles, stopping medications, having more satisfying social contacts, being able to work, finding a partner, etc. Clarifying and discussing individual goals for surgery early in the evaluation process helps to tailor the surgical procedure to the specific needs of the patient and also to uncover unrealistic expectations that will invariably create disappointment after the surgery regardless of its success as defined by "objective" criteria. For example, a patient whose primary motivation for undergoing epilepsy surgery is to drive motor vehicles will likely not be satisfied if he or she has a postoperative visual field defect that prevents driving, even if he or she becomes seizure-free.

Specific Risks of Epilepsy Surgery

In addition to the general surgical risks related to the procedure itself which do not differ from those of other neurosurgical interventions, there are some specific risks of epilepsy surgery that merit consideration, because they have the potential to impact the patients' postoperative quality of life yet are difficult to quantify in terms of either probability or magnitude.

Postoperative Neurological or Neuropsychological Deficits ("Functional Trade-Offs")

As mentioned before, epilepsy surgery often involves resection of functional cortex, which may cause postoperative neurological or neuropsychological deficits such as a worsening of memory in the case of mesial temporal lobe resections or a worsening of motor function in a resection involving primary motor areas. Other neurological or neuropsychological deficits may occur, according to the function represented in the area to be resected. Even in the (hypothetical) case of a certain outcome in terms of seizure freedom, intentionally creating a functional deficit conflicts with the principle of non-maleficence (first, do no harm). It can be ethically justified to override this principle if the expected benefit to the patient outweighs the harm caused by the deficit. There is, however, no general rule how to value the harm caused by an iatrogenic neurological deficit relative to the harm caused by seizures; this is an individual assessment and has to be discussed and agreed upon with the patient. Given the devastating physical and social effects of uncontrolled epilepsy, some patients are willing to sacrifice a considerable amount of function to be relieved of their seizures, but it has to be borne in mind that the seizures are a known entity whereas the impact of the functional deficit may be difficult to anticipate. Outcome research suggests that postoperative neurological deficits only become relevant in terms of quality of life when the patient is not seizure-free (Langfitt et al. 2007). However, given that the chance of postoperative seizure freedom is not 100 %, the risk of becoming a "double loser" has to be considered.

Uncertainties Regarding the Extent of the "Epileptogenic Zone"

The precise extent of the epileptogenic zone is unknown and can only be approximated prior to surgery. This implies a risk of over- or underestimation during the presurgical evaluation process. If the patient is seizure-free after the surgery, the epileptogenic zone is by definition included in the area that has been resected. However, it is possible that a smaller resection may have achieved the same result. This becomes ethically relevant if the resection can cause a neurological deficit. If the extent of the epileptogenic zone is underestimated, the chance of seizure freedom decreases. If it is overestimated, the risk of neurological deficits increases. This dilemma cannot be solved; only its impact can be minimized through the application of professional knowledge. In any case, the potential implications have to be discussed with the patient. Sometimes a two-stage procedure is advocated, undertaking first a smaller resection, with the option of a second, larger, resection if the patient is not seizure-free. This approach minimizes the risk of neurological

deficits but adds the general risks of an additional surgical procedure, as well as the risks due to continuing seizures. Again, this valuation requires a thorough discussion with the patient.

Postoperative Maladaptation ("The Burden of Normality")

It is a declared goal of epilepsy surgery to improve the patient's quality of life by increasing independence and reducing social limitations, but even in the case of successful surgery, the transition to a life without seizures does not always go smoothly. On the one hand, it is not uncommon that patients enter a period of euphoria after surgery which may lead to reckless behavior, creating new health hazards and social conflicts. On the other hand, patients with a long history of epilepsy often have difficulties to discard the "sick" role and adjust to new demands placed upon them (Wilson et al. 2001). The postoperative adaptation process requires time and is prone to disappointment if the "new life" is less satisfactory or takes more time and effort to manifest than has been anticipated. This in turn can influence the perceived success of the procedure.

The Importance of the Multidisciplinary Team

At the end of the evaluation process, an individualized treatment recommendation needs to be formulated. In general terms, potentially curative procedures should take precedence over palliative procedures and the lower the expected benefit in terms of seizure freedom and improvement of quality of life, the lesser the amount of risk that can be tolerated. This may include declining surgery if the perceived benefits do *not* outweigh the risks.

To ensure appropriate decision making, it has to be kept in mind that epilepsy surgery is a multidisciplinary effort. There is an old saying that "to somebody who has a hammer, everything looks like a nail." This also applies to medical professionals in that they have an inherent bias to favor the treatment they are knowledgeable of. In addition, individual physicians or surgeons have personal aims and preferences that may conflict with the patient's best interest. In order to avoid a technical or procedural imperative and to achieve the best possible outcome for the patient, individual expert knowledge has to be balanced by input from other team members with different expertise and points of view. Only when all aspects of the disease and the patient's situation have been considered, a largely unbiased recommendation for the individual patient can be formulated. As a consequence, everybody who has a stake in the presurgical evaluation should also have a word in the decision-making process. In addition to the neurosurgeon(s), this includes neurologists or neuropediatricians, neuroradiologists, neuropsychologists, psychiatrists, as well as social workers in order to facilitate the postoperative transition into a more fulfilling life. Therefore, the final decision whether a patient is a candidate for epilepsy surgery, and which procedure is deemed to produce the most benefit, should be taken by an interdisciplinary patient management committee.

Informed Consent

Once it has been determined that a patient is a candidate for epilepsy surgery and which procedure to recommend, informed consent has to be obtained. The purpose of informed consent is to safeguard patient autonomy in deciding what can be done with their body (or brain, in the case of epilepsy surgery). Autonomy means that an individual is able to act in accordance with a self-chosen plan, free from controlling interference by others as well as from limitations, such as inadequate understanding, that prevent meaningful choice (Beauchamp and Childress 2009). Therefore, the necessary components of legally and ethically valid informed consent are (1) competence, (2) disclosure, (3) understanding, (4) voluntariness, and, finally, (5) consent.

The following refers mainly to patients able to decide for themselves, but its general principles also apply to patients unable to provide legally valid consent and their caregivers or surrogate decision makers. Some specific issues regarding legally incompetent patients, including children, will be discussed at the end of this section.

In order to provide full disclosure, the following elements need to be discussed:

- The patient's epilepsy syndrome and its prognosis
- The recommended surgical procedure – how it is performed, the intended benefits, its likelihood of success, and potential risks
- Possible alternative approaches
- The risks of *not* undertaking the surgery

The physician obtaining consent should have a clear recommendation, be able to elucidate how this recommendation has been reached, and provide competent answers to all possible questions by the patient. This requires first of all that he or she is truly knowledgeable of all the elements stated above. In this regard it may be helpful to have both the neurosurgeon and the neurologist or neuropediatrician participate in the informational exchange.

A structured approach to obtaining patient consent is recommended, but this does not mean the procedure should be overly standardized. Published outcomes provide a useful framework to explain the general chances and risks of the planned procedure, but patients are unique and no two epilepsy surgeries are equal. Interviews with patients have shown clearly that they desire information to be as individualized as possible (Choi et al. 2011). Since outcomes can differ according to experience, the personal experience of the surgeon with this type of surgery should also be included.

When discussing risks of complications with the patient, all generic and specific risks as mentioned previously have to be mentioned. Rare but potentially serious complications should not be neglected. The fact that a serious complication is very rare will become irrelevant for the individual who has to face it. Finally, possible alternative treatments and their chances and risks need to be covered. The risks of *not* undertaking the procedure (i.e., morbidity and mortality due to ongoing seizures) have to be considered as well.

When patients are educated about the implantation of electrodes for diagnostic purposes, it has to be made clear that this does not automatically lead to a resection

and that the final decision can and should be taken only when the results are available. However, essential information about the possible resection should be given beforehand to prevent information overload before the final surgery when decisions may have to be taken under time pressure.

While uncertainties and risks should be clearly stated, being too detailed or presenting too much unstructured information can produce an equation with an unmanageable number of unknowns. Juggling probabilities and weighing uncertainties requires an amount of abstraction not all patients are used to or capable of. Psychological research has shown that human beings are subject to a number of cognitive illusions and biases when elaborating information that can impair informed decision making (Levy 2012). All these biases are accentuated by information overload and time constraints. Therefore, patients tend to extract whatever information they are able (and want) to understand and retain and much depends on how it is presented. In this regard it has to be emphasized that it is the responsibility of the physician obtaining legally binding consent to deliver the pertinent information in a way that the patient is able to understand and to verify what he or she has actually understood; otherwise, there is no informed consent. Ideally, the patient's goals and expectations have been clarified already during the presurgical evaluation, but the preoperative consent procedure is also the last chance to check for unrealistic expectations that can impact patient satisfaction after the surgery. This may include trying to modify the patient's expectations by providing further education and sometimes even imposing unwelcome information if this is deemed to be in the best interest of the patient.

As far as voluntariness is concerned, it has to be kept in mind that patients with drug-resistant epilepsy, like most other patients with chronic illnesses that bring about considerable impairment, are vulnerable to undue influences. In a vulnerable individual, decisional autonomy can be compromised in various ways (Ford 2009). There is a knowledge and status gap as well as a relationship of trust between physicians and patients that invites deferential acceptance of the physicians' recommendations. The lack of alternatives in patients who have exhausted almost all therapeutic options can result in desperation, leading to the acceptance of more risks or lower chances of success than would otherwise be the case. Situational vulnerability may ensue in relation to their social or physical environments. For example, patients may depend on caregivers who have their own interests at stake. Time constraints in decision making, such as when a patient is undergoing invasive monitoring with implanted electrodes which can remain in place only for a limited time, accentuate these vulnerabilities.

While patient vulnerabilities and cognitive biases cannot be neutralized completely, the treating physicians should make every effort to minimize their impact. In addition to awareness of their existence and good communication skills, the most important antidote is *time*. Informed consent is a process that is concluded the day before surgery, but education should begin much earlier. Overall, it is a good idea to address the possibility of surgical therapy already early in the disease, as soon as it becomes clear that drugs do not sufficiently control the seizures. Throughout the presurgical evaluation phase, information from different

sources can then be added on as it emerges, leaving time to digest it, formulate questions, talk to other patients who have undergone the same procedure, obtain a second opinion from experts in the field not directly involved in their care, and eventually adjust expectations.

Patients Who Are Unable to Consent

The level of competence of adult patients, meaning the ability to understand relevant information and make adequate decisions, has to be determined by the treating physician(s). If competence is found to be lacking, a court-appointed surrogate decision maker is needed to provide legally valid consent. For children who have not yet reached the legal age of consent (which may vary according to the country where they live), the decision makers are usually the parents.

Children and adult patients with reduced mental capacities are particularly vulnerable, because their understanding is limited and they are dependent on caregivers. However, the fact that a patient cannot provide legal consent does not mean that he or she is devoid of all decisional capabilities. Mental capacity is a continuum, and the informed consent process should be guided by respect for the patient's individual abilities. Especially children often understand more than adults think and are able to make quite reasonable choices (Alderson 2007). Children as well as incapacitated adults should therefore be involved in the consent process according to their ability, which requires an effort to deliver the relevant information in a way that they can understand. In most cases, at least assent to the procedure can be obtained. Elective surgery should not be performed against the patient's stated will. If a legally incompetent patient refuses to undergo a procedure thought to be in his or her best interest, further education needs to be provided.

A surrogate decision maker is appointed to act in the patient's best interest. Ethical challenges arise whenever it cannot be known what the patient wants, as with small children or adults with very limited mental capabilities. In this case the decision maker has to act in what is *presumed* to be the patient's best interest, which becomes the more difficult the higher the risk or the degree of uncertainty in terms of outcome. Especially parents who have to decide on a surgical procedure involving possible trade-offs in terms of neurological function face a daunting task. On the one hand, early surgery can help to prevent further deterioration through continuing seizures and medication side effects, and the plasticity of the developing brain promises better functional recovery after the surgery. On the other hand, parents are understandably reluctant to take responsibility for inflicting a possibly irreversible neurological deficit on their child, and some would like to postpone this decision to a later date when the child can decide for him- or herself. Another issue that may arise in the case of severely incapacitated patients is whether and to which extent it is legitimate to consider the caregiver's interests. While the patient's quality of life should not be confused with the value of the patient's life for others, it may be argued that alleviating caregiver burden will also benefit the patient.

Whenever the physician obtaining consent has the impression that surrogate decision makers are overwhelmed by their task or conflicts of interest ensue, an ethics consultation should be obtained to provide guidance. Sometimes the court will have to decide.

Contents

Abstract

Functional neurosurgery became one of the most dynamic fields in surgery developing from a subdiscipline to a major driver of innovations and novel therapeutic interventions. Despite an inglorious history rooted in unspecific psychosurgical lesioning techniques, functional neurosurgery has evolved to a

highly precise intervention based on cutting edge imaging, image guidance, and physiological technology offering the last treatment resort for a growing number of neurological and psychiatric indications. Novel devices including closed-loop systems for neuromodulation and prosthetic control promise further new treatment options in the near future.

These dynamic developments are changing the traditional field of related ethical issues significantly. This necessitates that functional neurosurgeons, patients, and society in general will have to deal with new ethical issues in the areas of neuroenhancement, privacy of brain-related information, and patient autonomy regarding control of implanted devices. These issues add to those already inherent to this discipline, e.g., challenges to neurosurgeons from the perspective of professional ethics in the specific context of brain intervention or adequate patient information about the increasing unpredictability of risks and benefits.

Functional neurosurgery will continue to open new doors of modulating brain function; concurrently arising ethical issues need to be addressed by ethicists and physicians jointly and ahead of time.

Introduction

This article on "ethics of functional neurosurgery" is divided in three chapters: core characteristics of functional neurosurgery, specific aspects of functional neurosurgery with ethical relevance, and discussion on general ethical questions.

The current focus of the ethical discussion about functional neurosurgery in literature is the stereotactic implantation of electrodes for deep brain stimulation (DBS). In the last decade more than 130 publications have been written on this topic, in contrast to only six publications on the ethics of functional neurosurgery (according to the data bank PubMed for the search terms "ethic*" $\wedge$ "deep brain stimulation" versus "ethic*" $\wedge$ "functional neurosurgery"). But functional neurosurgery is more than DBS. Although DBS is the most common intervention in functional neurosurgery, it is only one of many techniques used in this field. Thus, the current perspective might mask fundamental anthropological and ethical issues which need to be addressed.

What Is Functional Neurosurgery?

The field of neurosurgery addresses diseases of the central and peripheral nervous system with a large variety of surgical techniques. In the majority of cases, neurosurgical interventions aim at removing pathologies such as brain tumors, vascular lesions, or degenerative tissue of the spinal cord. These "morphological" approaches to diseases of the nervous system have been extended especially in the last two decades by "functional" approaches. Due to neurotechnological developments and a deeper understanding of the neurophysiology of diseases, many new approaches arose modulating "functionally" the nervous system, e.g., in movement disorders

(Elder et al. 2008; Sachdev and Chen 2009; Missios 2007). Hence, these new approaches have to be addressed from an ethical perspective as well.

The term *functional neurosurgery* was coined by Lériche and Wertheimer around 1950, stressing the importance of exploiting neurophysiological knowledge for interventions aimed at changing the dynamics of a system. According to this concept, the "aim and objective of functional neurosurgery are to treat, correct, or balance the functions of the brain that are altered toward either hyperfunctional or hypofunctional states." (Marino 1979). This can result in "positive" or "negative" symptoms and is closely linked to a functional account of disease as exemplified by Boorse. He defined a disease as a "type of internal state which [...] reduces one or more functional abilities below typical efficiency," (Boorse 1977) relating functional abilities to the concepts of reference class and normality: "The reference class is a natural class of organisms of uniform functional design; specifically, an age group of a sex of a species," while "a normal function of a part or process within members of the reference class is a statistically typical contribution by it to their individual survival and reproduction" (Boorse 1977). This approach to the design of neurosurgical interventions necessitates an explicit view of the central and peripheral nervous system as a *dynamical system*. In the same way as the "origin of disequilibrium may be vascular, tumoral, degenerative, or infectious and it may or may not require specific treatment," (Marino 1979) the actual intervention might be targeting a different function located at a different brain area to reestablish normality. In that regard, functional neurosurgery is not a specific technique but a family of methods to modulate functionality with implants in the central or peripheral nervous system.

For this goal, knowledge about the location of functions of the nervous system and their interaction in a network has to be applied with high sensitivity and specificity for each individual patient. Because of these three aspects (localization, system, and subject-level accuracy), presurgical planning and intrasurgical monitoring are of tremendous importance (Ford and Kubu 2005; Kekhia et al. 2011; Borchers et al. 2012; Martino et al. 2011). Functional neurosurgery is therefore highly interested in any advances made in functional brain mapping and neuroimaging which could guide treatment and result in knowledge about biomarkers of disorders (Martin 2012). The fourth important aspect is the increasing understanding of the method of action of these interventions to the nervous system (Cheney et al. 2012; Kringelbach et al. 2010; Dzirasa and Lisanby 2012). This allows functional neurosurgery to improve its tools based on the expected effects of different interventions (Martin 2012; Min et al. 2012). With new technological tools for manipulating functionality and a scientific understanding of the method of action at hand, modern functional neurosurgery has tremendously evolved since the beginnings when therapeutic lesions were applied (Synofzik and Schlaepfer 2008).

Three Main Characteristics

With this in mind, we argue that modern functional neurosurgery is defined by three key characteristics. The first is the concept of *operative neuromodulation*, which is an "interventional field of medicine that alters neuronal signal transmissions by implanted devices, either electrically or chemically, in order to excite, inhibit or

tune the activities of neurons or neural networks to produce therapeutic effects." (Sakas et al. 2007). [S4] The second is the concept of *closed-loop stimulation* which is often also called smart, intelligent, individualized, or on-demand brain stimulation (Benabid et al. 2011; Modolo et al. 2012). The common strategy behind these terms is to monitor online neurochemical (Shah et al. 2010) or neurophysiological activity (Berenyi et al. 2012) for real-time adaption of brain stimulation parameters. The third is the concept of *neural interfacing and prosthetics*, which includes two aspects: the possibility of real-time translation of signals from the nervous system into information which can be utilized for communication, control, or biofeedback (Daly and Wolpaw 2008) and the ability to replace neurological functions such as speech, motor, sensory, hearing, or vision with prosthetic devices at the cellular or systems level (Wang et al. 2010; Stieglitz 2007).

Examples for *operative neuromodulation* are deep brain stimulation (DBS) and epidural motor cortex stimulation (EMCS), which are used in the treatment of Parkinson's disease (Gutiérrez et al. 2009; Fasano et al. 2012), dystonia (Pagni et al. 2008; Vidailhet et al. 2012), or pain (Stadler et al. 2011). Developments of *closed-loop stimulation* are currently evaluated in Parkinson's disease (Tsang et al. 2012; Lee et al. 2009; Priori et al. 2012), pain (Zuo et al. 2012), and epilepsy (Berenyi et al. 2012). Research on *neural interfacing and prosthetics* is addressing speech, e.g., in patients suffering from amyotrophic lateral sclerosis (Brumberg and Guenther 2010) or motor control in patients with spinal cord injury (Bhadra and Chae 2009).

In this context, irreversible therapeutic lesioning is a last resort in functional neurosurgery and results often from insufficient knowledge, technical and financial limitations, or pressing medical needs (Raoul et al. 2009). In contrast, functional neurosurgery aims to keep the anatomy intact and to achieve therapeutic gains by modulating pathological functions. Most other branches of neurosurgery explicitly change anatomy, and obviously, the removal of pathological brain tissue might result in functional improvement as well. Nonetheless, such interventions would be attributed rather to classical general neurosurgery than to functional neurosurgery.

Specific Aspects and Differences to Other Medical Interventions

Although principles from general medical ethics are applicable to functional neurosurgery, this discipline is in many aspects different from other medical specialties. Special attention should be given to the fact that functional neurosurgery is a surgical intervention, usually in the brain, with an infamous history in the era of irreversible brain lesioning. At the same time, while being a last resort for many disorders, it offers unique opportunities for a deeper understanding of brain functioning and disease.

It Is a Surgical Intervention

Any intervention in functional neurosurgery is essentially a surgical one. Therefore the topic of the invasiveness of the intervention is of importance.

Additionally, because the anatomy of every patient is very individual, there is a high need for correct localization. Presurgical mapping based on functional magnetic resonance imaging or transcranial magnetic stimulation becomes increasingly unreliable after the dura has been opened. "Following opening of the dural flap, surgical manipulation, CSF drainage, edema, and issues related to gravity and positioning cause the brain to shift, causing an anatomic discrepancy between the preoperatively acquired images and the surgical field. This displacement is exacerbated by the progression of the surgical procedure." (Kekhia et al. 2011). From this perspective, stereotaxy is only one of the many options available to the functional neurosurgeon to ensure correct targeting. Usually, the neurosurgeon also relies on intraoperative measurements, e.g., spiking activity, local field potentials, or direct cortical stimulation. Because of the brain shift and the potential unreliability of presurgical maps, intraoperative measurements and events have to be interpreted on the spot and a need for adaptation may arise during surgery, also in the case of unplanned complications. This has an influence on how strong a neurosurgeon can rely on evidence-based knowledge for guidance. Often, a surgeon's professional experience and know-how to employ his individual skill and judgment in unique cases must be balanced against a need to generalize knowledge and provide best care for groups of patients (Ford and Henderson 2004). Essentially, functional neurosurgery is a practice with a large heterogeneity between centers (Abosch et al. 2012), and its safety and efficacy relies heavily on the experience, competence, and decisions of the individual surgeon (Kleiner-Fisman et al. 2006; Kirsch and Bernstein 2012). Additionally, many of the functional measurements during the surgery make it necessary that the subject is awake. This presents several unique challenges. Insensitive comments by the staff will be overheard or the patient might misinterpret professional conversation. It is therefore important how patients perceive the surgical team, but this also puts the staff under scrutiny and increases their mental load. Awake surgery can also mean that consent is withdrawn during the intervention (Kirsch and Bernstein 2012).

It Is a Last Resort

Any surgery carries an inherent risk of adverse events of different severity. Adverse events can be attributed to one of three domains. They are either related to the surgery (e.g., transient confusion, hemorrhage, infection, seizures), to the device (e.g., dysfunction, replacement, infection, or migration), or to the modulation (e.g., cognitive, emotional, behavioral, or motor problems) (Kleiner-Fisman et al. 2006). Naturally, surgical risks increase from transcranial (essential noninvasive) to epidural to subdural to subcortical interventions. Complications during surgery can result in severe extension of duration and put a high toll on the stamina of the surgeon. At the same time, this need for individual decision making and the immediate perception of consequences of surgery mean that issues of adequate training, physical ability, professional responsibility, and coping with feelings of guilt present themselves in a special manner in neurosurgery. The challenge for the

surgeon is to trust in one's abilities while being able to perform a critical self-assessment. "All surgeons reach an age when the technical competence and personal stamina necessary to perform surgical procedures may decline. We are responsible to adjust our activity as appropriate when that time occurs." (Umansky et al. 2011). Yet, risks for adverse events during surgery are not only attributable to the surgeon, but are mediated by several factors. Age, neurovascular disorders, other comorbidities, and the psychosocial state of the patient are essential aspects for any consideration of surgery. Therefore evidence-based inclusion and exclusion criteria should be developed to guide risk-benefit assessments. Additionally, there is an inherent, irreducible risk of mortality and permanent impairments. Functional neurosurgery is therefore by many considered to be a last resort treatment when the patient has been shown to be refractory to other treatments. Yet, in many disorders early intervention is being considered. In Parkinson's disease, there is the possibility of a neuroprotective effect and the prevention of psychosocial problems (Schermer 2011); and for amyotrophic lateral sclerosis, the early implantation of communication prosthetics might be necessary to prevent the extinction of thought in a completely locked-in state (Murguialday et al. 2011). Additionally, the different levels of invasiveness should be weighed against the potential benefit.

It Is an Intervention in the Brain

To common understanding, cognitive, sensory, and motor functions are manifested in the nervous system. Functional neurosurgery builds on the assumption that these properties can be localized and modulated. At the same time, the brain has a unique role for most individuals, and also in our society, and is therefore perceived as fundamental for the understanding of personhood. "Recognizing that the brain has a central importance in the organization of patients as persons makes performing brain surgery perceptively different from other types of surgeries." (Ford and Henderson 2004). In parallel, medicalization in the context of a professional interaction is characterized by a low responsibility of the patient for the onset and solution of a problem, but a high expectation to follow the advice of an expert (Brickman et al. 1982). At the same time, neuroscience has a big impact on our concepts of personhood (Farah and Heberlein 2007) and responsibility (Walter 2001), and the topics of medicalization, localization, reification, and exoneration (Fuchs 2006) are ever present. We believe that in many medical specialties, these topics are of reduced presence. But the strong foundation of functional neurosurgery in neuroscience, its high spatial accuracy, the praxis of surgery, i.e., the process of interaction with immediate consequences, and the strong medical primer of a surgery make it next to impossible to ignore these aspects. Therefore the framing of a treatment as "intervening in the brain" (Merkel 2007) or a disease as a "brain disorder" (Leshner 1997) based on functional neuroimaging (Ford and Kubu 2005) changes the perception of the stakes at hand.

It Is an Opportunity for Research

Additionally, any functional intervention in the brain is an opportunity for research and a better understanding of the human nervous system. This research happens as a fundamental part of functional neurosurgery, e.g., when activity in subcortical areas is measured to improve targeting during DBS implantation (Seifried et al. 2012). It can also be a result of postoperative evaluations and help detecting biomarkers of disorders (Bronte-Stewart et al. 2009) or be used for research of functions not directly affected by the disorder (Shibasaki 2012). Balancing the opportunity for research with the best interest of the patients can be a fine line. Patients might feel compelled to satisfy the demands of the clinical personnel or confuse research with a measurement necessary for medical treatment. At the same time, many interventions proposed as treatment are currently still under research. Patients, but also clinicians, can be desperate after unsatisfactory treatments, and the opportunity to take part in a clinical study or explore a novel treatment might feel very compelling in spite of the unknown dangers. Patient autonomy in this regard is therefore no fail-proof guardian against unnecessary or disproportionate risks. On the other side, many neurological disorders such as degenerative disorders or stroke often result in chronic, functional impairments which cannot be treated sufficiently with classical therapeutic approaches. In addition, accidents may result in amputations and losses of sensory organs. Therefore, anyone can get in need for novel functional rehabilitation approaches. Thus, if functional restoration might only be achieved with a neurosurgical intervention and prosthetic approaches, many people will take that risk. This development will be fueled by technological breakthroughs supported by respective funding agencies (Judy 2012).

It Has an Infamous History

Almost no ethical paper in the literature discusses DBS without mentioning the term psychosurgery. Egas Moniz suggested in 1935 the ablation of the frontal cortex as a treatment option for psychiatric disorders which were otherwise treatment resistant. In 1949 he won the Nobel Prize in medicine for this approach. Walter Freeman and James Watts simplified the approach to transorbital frontal lobotomy, on which the infamous story of the ice pick through the eye is being based. From 1945 to 1955 tens of thousands of patients were treated by this crude intervention (Tye et al. 2009). Relatively poor hygienic standards, the conduction with insufficient surgical training, lacking follow-up, and severe side effects resulted in increasing criticism.

Modern functional neurosurgery takes a completely different approach. Many authors see the development of stereotactic procedures as a reaction to the crudeness and high morbidity of lobotomy (Krack et al. 2010). Others see the origin of functional neurosurgery in brain stimulation studies, e.g., in electroconvulsive therapy (ECT) introduced by Ugo Cerletti in 1938 for the treatment of severe psychosis (Sironi 2011), and in reports on intracranial stimulation of the median

forebrain bundle in rats (Appleby and Rabins 2009). Hence, “ablative surgery and electrical stimulation developed in parallel, practically since the introduction of human stereotactic surgery” (Hariz et al. 2010). After high-frequency DBS was introduced and shown to mimic the effect of a lesion, the field of functional neurosurgical interventions changed drastically, as it allowed for adaption of stimulation, reversibility, and reduced morbidity (Benabid et al. 2009a). It should therefore be noted that comparing modern functional neurosurgery to early psychosurgery is wrong in many regards. Modern functional neurosurgery is based on informed consent, clearly defined inclusion and exclusion criteria, clinical decision making by an interdisciplinary team, reversibility and precise targeting, and neuroimaging (Synofzik and Schlaepfer 2008). The comparison of functional neurosurgery to ECT, mind control, or psychosurgery only feeds ungrounded fears (Clausen 2011) and is very unfortunate (Synofzik and Schlaepfer 2008). Yet, the other side of the coin is the hyperoptimistic presentation of DBS in the media (Gilbert and Ovadia 2011).

Ethical Questions

General medical ethics is based on the principles of beneficence, non-maleficence, patient autonomy, and justice (Beauchamp and Childress 2009). These principles also apply to functional neurosurgery. Neuroenhancement and privacy are additional issues that have to be addressed with regard to functional neurosurgery. These issues will be discussed in this chapter.

Beneficence, Non-maleficence, and Cost-Benefit Analysis

Beneficence and its antonym maleficence can be integrated into the concept of a cost-benefit analysis. Due to the large number of interventions possible in functional neurosurgery, a detailed analysis for each intervention is beyond the scope of the present article. As already explained, risks can be related to the surgery, the device, or the modulation. For functional neurosurgery, two aspects are specifically important. First, regular follow-ups are necessary to achieve and maintain the gains of the intervention. This should be factored into any analysis, e.g., by assessing social or familiar support or the distance of the patient’s home to the treating institution for regular follow-ups. Second, a surgery involves not only certain costs, but also risks and uncertainties. Even if a certain treatment would show to be effective in every case, there would still be a risk for a negative outcome due to complications related to the surgery. Therefore, these surgeries cannot be expressed uniquely in cost-benefit analyses, but need a risk assessment as well. As these risks may be related to patient-specific criteria, this means that a reliable cost-benefit analysis can only be performed if definite patient inclusion and exclusion criteria have been established. Yet, humans are notoriously bad at judging and perceiving risks (Lloyd et al. 2001), this is true for both patients and

surgeons. Moreover, quantitative statements may confuse rather than inform those not familiar with these statistical information (Schwartz 2011). It is known that surgeons may suffer from overconfidence in their ability to reduce risks (Kissinger 1998). All these aspects have a direct impact on how patients should be informed for their consent to the intervention.

Autonomy

Every medical intervention needs informed consent, which "implies three basic requests: (1) all medically relevant information about diagnosis and prognosis of a patient's disease, the therapy, its potential risks and alternative therapies must be disclosed. (2) The patient should have the mental capacity to understand his or her situation and the presented information. (3) The patient must not be coerced or compelled, but autonomously decides about a treatment on the basis of the information disclosed." (Skuban et al. 2011). Yet, autonomy in the context of functional neurosurgery faces some special considerations. Many functional neurosurgeries are performed with awake patients. That means, that consent could be revoked at any time during the procedure. Although rare, such cases have been documented. Rules need to be put in place to deal with this situation. Patients may be more likely to suspend a surgery once informed of this option, and surgeons should consider discussing how requests for discontinuation will be handled. Guidelines regarding advanced directives, appropriate intraoperative measures of persuasion, and the possibility of returning to surgery at a later date need to be developed. If the patient would benefit greatly from an intervention, a higher level of convincing might be mandated. Additionally, functional neurosurgery often relies on implanted devices that are in need of ongoing maintenance and professional supervision. Withdrawal of consent by the patient or reduced compliance can result in medical problems and could happen at any time. This withdrawal poses an ethical challenge. In functional neurosurgery, ending treatment will be realized by turning off the device. But in some cases, explantation of the device might be considered – resulting in additional risks. On the other side most of the implantable devices allow for fine-tuning. How much freedom should patients have in changing the parameters of these devices knowing that too much freedom may result in abuse, e.g., self-stimulatory behavior in DBS (Morgan et al. 2006)? At the same time, informed patients' control over the device may reduce side effects of the stimulation and save battery life.

Privacy

With many implanted devices, neuronal activity is constantly monitored during regular activity of the patients. This is commonly the case with electrodes implanted for epileptic diagnostics, but storage is also necessary for many other neural interfaces. Additionally, one might consider other types of data stored in implanted devices, e.g., kinematic data. Already, commercial use of

brain-computer interfaces spawn discussions about side-channel attacks (Martinovic et al. 2012). Data security against malicious intrusion might therefore be topic in the development of safe readouts from implantable devices. There are also non-malicious dangers to privacy. Stored data could be used as evidence in a law trial, and the device could be exploited as a lie detector (of uncertain accuracy). If any information stored in the device is being "disclosed without proper consent, such information could lead to unanticipated insurance, employment, or legal problems for the individual" (Wolpe et al. 2010).

Neuroenhancement

Neuroenhancement has been defined as any "technical intervention aimed at improving some physical or psychological aspect of an individual, but which cannot be categorized as treatment" (Merkel 2007). Currently, to our best knowledge, no functional neurosurgery has been performed worldwide on healthy subjects. It is therefore unknown whether a specific treatment improving functionality in a pathological state might also show efficacy in healthy subjects. That makes it difficult to assess whether neuroenhancement is even feasible. Currently, in the field of *neural prosthetics*, an artificial enhancement is unlikely as any sensory or motor replacement today cannot compete with the original, healthy organ. Yet, additional senses or brain outputs could be an option for enhancement. Brain-computer interfaces used, e.g., for controlling a cursor on the computer screen, already work in healthy subjects with noninvasive recordings (Wolpaw 2007; Silvoni et al. 2011). Invasive recordings would improve the accuracy, speed, and flexibility of the device. Also, noninvasive neuromodulation has been shown to improve a whole range of cognitive and motor functions (Hamilton et al. 2011), from working memory (Polanía et al. 2012; Zaehle et al. 2011) or sensory discrimination (Ragert et al. 2008) to motor performance (Joundi et al. 2012). *Operative neuromodulation*, maybe in combination with *closed-loop stimulation* adapted to the individuals' anatomy and cerebral networks, might further exploit these effects. In the course of a regular treatment, it could happen that a further (or the same) functionality may be improved above the average, an effect coined incidental enhancement by Peter Kramer (Kramer 2009). In depression treatment, mood could be improved above average; in treatment of spinal cord injury, external gadgets could become controlled directly, and in treatment of blindness, additional spectra could be included.

We therefore have no doubt that neuroenhancement with functional neurosurgery is theoretically possible (albeit risky). Therefore, this option might generate a demand. Applications in healthy subjects might be funded by the military. Or wealthy individuals with a transhumanist agenda could start recruiting their own neurosurgical staff. Even when stipulating that "enhancements which cannot at least count as prevention of disease/disability [. . .] should not be included in the sphere of proper medicine as a social system," (Merkel 2007) dealing with privately paid functional neurosurgery may become an issue in the future. Just as plastic surgeons "shifted from reconstructive to cosmetic procedures," (Hamilton et al. 2011)

a similar fate might occur in neurosurgery. Sliding down a slippery slope (McNamee and Edwards 2006) or thanks to a "diagnostic bracket creep," (Kramer 2009) they could become "future providers of neuromodulation technology." (Mendelsohn et al. 2010). From an ethical perspective, that means that it will be important to consider how to deal adequately with such possible developments in advance.

Distinguishing the enhancement of cognitive and motor skills from the modulation of emotion and motivation might be of ethical relevance. Many ascribe the latter functions as more relevant role for the concepts of personal identity (Jotterand and Giordano 2011) or authenticity (Leefman et al. 2011). At the same time, these functions are located more in deeper brain structures (Cardinal et al. 2002); hence, no consistent influence of noninvasive neuromodulation has been shown so far (Hamilton et al. 2011). These targets might be achieved by functional neurosurgery. This means that the issues of personality changes, personhood, authenticity, and personal identity will gain more importance in the assessment of neuroenhancement in this context.

Justice

A main argument against research on functional neurosurgery is that it is too costly and drains funds from established treatments. This concern has, e.g., been expressed against the research of DBS for the treatment of addiction: "The addition of an expensive neurosurgical treatment that costs of the order of US$50 000 (with maintenance costs of approximately US$10 000 every few years) will worsen this situation by utilizing scarce health resources to treat a very small number of patients with the income to pay for it" (Carter and Hall 2011). For many functional neurosurgical interventions, this argument does not hold. DBS, for example, is cost-efficient for addiction (Stephen et al. 2012) and for Parkinson's disease (Valldeoriola et al. 2013). Yet, most DBS surgeries are performed in large teaching hospitals in metropolitan areas (Lad et al. 2010), possibly indicating differences in regional availability of this treatment option. The relative high costs of stimulation devices make it certainly difficult to propagate DBS as a replacement for therapeutic lesions in developing countries (Benabid et al. 2009b), especially when there is already a lack of receiving basic care in these areas (Rosenfeld et al. 2008). At the same time, vulnerable patients from wealthy countries might decide traveling to countries with a lower standard of ethical or scientific scrutiny paying for treatments without any proven benefit (Rosenfeld et al. 2008).

Conclusion

What has already been achieved with functional neurosurgery was a science fiction only a decade ago. Robotic limbs are controlled by thoughts, implanted devices change mood and influence motor skills, and sensors constantly record brain activity and modulate it. We believe that the topics of privacy, autonomy, enhancement, and

individual benefit are already in the focus of functional neurosurgeons. On the other side, while there is awareness that global justice and a fair distribution of health resources are important, these topics receive relatively little attention. Probably this will be one of the issues that will be tackled in future together in the context of studies on the socioeconomic impact of operative neuromodulation, closed-loop stimulation, interfaces, and prosthetics. With the words of William Gibson, "the future is already here – it's just not very evenly distributed."

Addiction and Neuroethics

What Is Addiction Neuroethics?

Adrian Carter and Wayne D. Hall

Contents

Abstract

Drug use and addiction are significant problems facing most societies. Neuroscience promises to reduce the incidence and harms of drug use through the development of more effective treatments targeted at changes in the brain produced by chronic drug use and by identifying persons most likely to develop harmful drug use and preventing them from becoming addicted. By locating the source of addictive behavior in the brain, neuroscience may be seen to account for some addicted individuals' criminal behavior and justify the use of coercive interventions to treat their addiction. Neuropharmacological interventions used to treat drug addiction may also be co-opted by healthy individuals to enhance their normal cognition. In this chapter we introduce the reader to *Addiction Neuroethics*, the ethical issues raised by proposed and potential applications of neuroscience research on addiction.

Addiction is a central topic in *Neuroethics*. Drug use and addiction are major problems facing most societies and one of the largest causes of preventable disease

burden worldwide accounting for over 10 % of the overall burden of disease in Europe and developed countries such as Australia, Canada, and the USA (Begg et al. 2007; ONDCP 2004; Rehm et al. 2005). Neuroscience research has begun to describe in great detail the impact of chronic use of drugs on reward systems in the brain that leads to addiction. Addiction also raises many neuroethical challenges, arguably more so than many other psychiatric or neurological disorders, because of the complex intersection of medical, social, and legal responses to a strongly socially disapproved form of behavior.

Addiction is typically defined as a persistent pattern of drug use in the face of harms caused to the drug user and others in their social environment, such as family, friends, workmates, and neighbors. There has been a long running opposition between moral and medical explanations of this pattern of drug use. A moral model describes addiction as a largely voluntary behavior in which people choose to engage (Heyman 2009), and hence, drug users who commit criminal offences should be prosecuted and imprisoned if found guilty. A medical model of addiction, by contrast, recognizes that while many people can use drugs without losing control over their use, a minority will develop a mental or physical disorder – an addiction – that undermines their ability to control their drug use and requires treatment if the sufferer is to become and remain abstinent (Leshner 1997).

Neuroscience research on addiction is seen as supporting a version of the medical model that explains addictive behavior in terms of changes in brain processes produced by chronic drug use (Koob and Le Moal 2006). If accepted, such causal accounts provide an alternative to the view that the use of addictive drugs is always a matter of individual choice. Proponents of the brain disease model of addiction believe that it will radically benefit social and public health policies towards addicted persons by providing more effective, humane, and ethical treatment of addicted persons (Dackis and O'Brien 2005; McLellan et al. 2000). These benefits will include:

- Less reliance on expensive punitive policies such as imprisonment
- More funding of addiction research and treatment services
- Greater access to treatment for those who are addicted
- Increased coverage of addiction treatment by insurance companies
- Greater investment in addiction treatment, research, and development
- Decreased stigmatization of addicted persons to reduce social isolation and increase treatment seeking
- A more rational approach to drug policy that reflects the impact of specific drugs upon the brain

Social scientists have highlighted potentially less welcome effects of neuroscience models of addiction on social and public health policy (Campbell 2012; Carter and Hall 2012; Midanik 2004). They argue that neuroscience research overemphasizes biomedical approaches to the treatment of addiction at the expense of psychosocial policies that aim not only to treat addiction but also to reduce drug use in society.

The five papers contained in this section of the *handbook* analyze some of the ethical and legal issues raised by neuroscience research on addiction and its current and future applications to treating and preventing addiction and developing social policies towards drug use.

Anne Lingford-Hughes and Liam Nestor provide an overview of neuroscience research on addiction (▶ Chap. 65, "Neuroscience Perspectives on Addiction: Overview"). They outline the types of research evidence that are used to support the claim that addiction can be usefully thought of as a "brain disease." This includes insights derived from influential animal models of human addiction, such as estimating the addictive potential of new psychoactive substances and identifying how these drugs act within the brain to change brain structure and function. They summarize recent neuroimaging studies of addicted persons which suggest that the findings from animal models of addiction apply in addicted humans.

▶ Chap. 66, "Ethical Issues in the Neuroprediction of Addiction Risk and Treatment Response" addresses the ethical implications of claims that neuroscience research will soon enable us to identify persons who are at greatest risk of developing an addiction. This research is often promoted as a way of allowing the development of social policies that will more effectively prevent addiction in persons at higher risk and match addicted individuals to the forms of treatment that are most likely to benefit them. Such proposals, should they prove successful, would raise ethical concerns, such as privacy and third party uses of predictive information and the use of preventive interventions without consent. In this chapter, Wayne Hall, Adrian Carter, and Murat Yücel review recent neuroimaging studies that are claimed to have identified markers of brain activity in persons who are most susceptible to developing an addiction. They begin by reviewing genetic research conducted with similar aims to see what might be gleaned from this experience about the likely utility of neuroprediction. They outline the technical and ethical challenges that remain to be addressed before neuroimaging technologies can be used either for preventive purposes or to match addicted persons to the form of treatment that is most likely to assist them to become and remain abstinent.

In ▶ Chap. 67, "Ethical Issues in the Treatment of Addiction," Benjamin Capps and colleagues examine the ethical issues that may arise in the application of knowledge from addiction neurobiology to the treatment of addiction. Their chapter covers ethical issues raised by the treatment of opioid and other forms of drug addiction using substitute medications; the use of drug vaccines and depot forms of antagonists to treat addiction; the use of invasive treatments to directly modify brain function, such as deep brain stimulation and neurosurgery; and the use of varying degrees of coercion, including legal coercion by the courts, to encourage addicted persons to enter addiction treatment.

▶ Chap. 68, "Drug Addiction and Criminal Responsibility" considers the implications of addiction neuroscience for the way in which the criminal law treats addicted offenders. Jeanette Kennett, Nicole Vincent, and Anke Snoek examine the bearing of neuroscience evidence on the assessment of the responsibility of addicted persons for their drug use and crime engaged in to finance it. They then consider the implications of this assessment for the use of imprisonment and legal coercion in the treatment of addicted offenders. They accept that the majority of addicted individuals do not suffer from a brain disease that overwhelms their autonomy but argue nonetheless that some severely addicted individuals do develop a brain disease that undermines their ability to control their drug use and reduces

their responsibility for some criminal acts committed to facilitate their addictive behavior. They provide results from interviews from a group of addicted individuals to support their thesis.

► Chap. 69, "Using Neuropharmaceuticals for Cognitive Enhancement: Policy and Regulatory Issues" examines possible regulatory approaches to the use of pharmaceutical drugs that are claimed to enhance the cognitive functioning in normal individuals, that is, persons who do not have cognitive impairment. Jayne Lucke and colleagues analyze current approaches to the regulation of psychoactive drugs that are used for nontherapeutic reasons, such as alcohol and tobacco, pharmaceuticals, and illicit drugs, and the possible implications of neuroscience research on drug addiction for the regulation of putatively neuroenhancing pharmaceuticals.

Contents

Abstract

Substance addiction can be a chronic relapsing disorder. While different drugs of addiction have different primary molecular targets, it has been demonstrated that many share the common action of being able to increase dopamine within hard-wired reward circuitry. While this effect is widely conceived as a primary factor driving initial drug use, long-term adaptations within this hard-wired neural circuitry underlie the transition from drug use to drug dependence. Significantly, these neuroadaptations are responsible for triggering recurrent drug relapse in people recovering from addiction, even when following periods of long-term abstinence. While there is no animal model of addiction that can fully emulate the human condition, some animal models do permit the investigation of specific elements of drug addiction, particularly those involving the reward system and its role in drug-seeking behavior. Neuroimaging methods now also permit us to test hypotheses of addiction derived from such animal models, allowing the field

of neuroscience to examine neural components of drug abuse and dependence in humans. These neuroimaging procedures permit neuroscientists to test hypotheses in humans at different stages of the addiction cycle, particularly with a view to developing better treatments.

Introduction

Substance addiction is often defined as a chronic, relapsing disorder characterized by (1) compulsion to seek and take the substance, (2) loss of control in limiting substance intake, and (3) the emergence of a negative emotional state (e.g., dysphoria, anxiety, irritability) reflecting a motivational withdrawal syndrome when access to the substance is prevented (defined as Substance Dependence by the 4th edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) of the American Psychiatric Association). Individuals meeting such criteria are those commonly described in clinical and neuroscience literature; however, many people do not enter such a chronic relapsing pattern and recover without treatment. Although drugs of addiction (e.g., alcohol, amphetamines, cocaine, nicotine) have varying pharmacological profiles, their ability to activate the mesocorticolimbic system is known to mediate their acute reinforcing effects (Koob and Volkow 2010). With chronic drug use, however, it is proposed that long-term neuroadaptations within this same mesocorticolimbic circuitry underlie the transition from drug use to drug dependence and relapse to drug use during abstinence.

Animal models have been critical in developing theories regarding the evolution of addiction. The positive-reinforcing effects of drugs of abuse (i.e., their ability to induce a conscious feeling of pleasure) have been widely conceived as a primary factor behind continued drug use and eventual drug dependence (Koob and Volkow 2010). Both positive and negative reinforcement theories additionally provide some insight into both the initiation (i.e., pleasure) and maintenance (i.e., withdrawal avoidance) of compulsive drug use (Cami and Farre 2003; Koob and Volkow 2010). Such theories, however, are unable to account for the resumption of drug-seeking and drug-taking behaviors (i.e., relapse) following protracted periods of abstinence. Chronic drug use has been proposed to result in a pathological shift in the hedonic set point of the drug user (Koob and Le Moal 1997). This state of dysregulation within evolutionary hard-wired brain reward systems is proposed to ultimately lead to a loss of control over drug use; that is, drug abuse produces a disequilibrium within brain reward circuitry that cannot be biologically maintained without using the substance of addiction.

An alternative theory is that addiction involves the development of "incentive sensitization" (Berridge 2009; Berridge and Robinson 1998; Berridge et al. 2009; Robinson and Berridge 2000). The chronic use of drugs is theorized to produce alterations in neural systems involved in the motivation and reward for natural appetitive reinforcers (e.g., food, water). Drug abuse is thought to induce a hypersensitive state to the drug and drug-associated stimuli (e.g., people, places,

and objects associated with the substance). This ultimately leads to a shift from drug "liking" to drug "wanting," whereby there is an ensuing compulsion to seek out and use the substance at any cost.

Additional theories view the persistent nature of addictive behaviors as ingrained drug habits in the form of aberrant stimulus response learning (Everitt and Robbins 2005; Volkow et al. 2006a; Wise 2002) and alterations in prefrontal cortical activity that reduce behavioral control and decision-making skills (Bechara 2005; Goldstein and Volkow 2002). Although each of these theories contributes its own unique perspective to the evolution of addiction, it is likely that there is significant overlap in these concepts. Furthermore, in humans, initial drug use probably involves a complex interaction between various components (i.e., biological, sociological, economic, legal, and cultural) that, in some individuals, produce substance addiction.

Pharmacology of Major Drugs of Dependence

Understanding the pharmacology of drugs of abuse is vital to improving the prevention and treatment of addiction (Nutt and Lingford-Hughes 2008; Lingford-Hughes et al. 2010). Drugs of abuse are commonly classified into major categories (Feltenstein and See 2008) that include narcotics (e.g., opiates such as heroin), cannabinoids (e.g., marijuana), depressants (e.g., alcohol), and stimulants (e.g., nicotine, amphetamines, cocaine). While these substances all produce feelings of pleasure and relieve negative emotional states, they also possess highly diverse behavioral effects due to their varied neuropharmacological profiles in the brain. The mesocorticolimbic dopaminergic system is a key target for all substances of abuse. Modulation of the dopaminergic system may occur directly, as in the case of stimulants that block the dopamine transporter (DAT) in the nucleus accumbens (e.g., cocaine) or stimulate dopamine release (e.g., amphetamine). It may also be indirect, by increasing dopaminergic neuronal firing via disinhibition of inhibitory gamma amino butyric acid (GABA) interneurons in the ventral tegmental area (e.g., alcohol, opiates, nicotine) (see Everitt and Robbins 2005).

A key modulator of mesolimbic dopaminergic function is the endogenous endorphin system. It is the major target for the opioid drugs such as morphine and heroin, and it has long been implicated in processes such as interpersonal bonding (e.g., mother-child), love, and reward. Opiates reduce anxiety and induce euphoria and sedation (Heishman et al. 2000; Hill and Zacny 2000) by activating opioid receptors of which there are three subtypes: the mu opioid receptor (mOR), kappa opioid receptor (kOR), and delta opioid receptor (dOR). The activity of opiates at the mOR subtype underlies their abuse potential. The mOR is located in a variety of brain regions, including the cerebral cortex, thalamus, hippocampus, locus coeruleus, ventral tegmental area (VTA), nucleus accumbens (NAcc)/ventral striatum (VS), and the amygdala. Opiates mediate their reinforcing effects directly in the NAcc at the mOR and indirectly through mOR inhibition of GABA function

on dopaminergic cells in the VTA, thereby increasing firing of dopamine VTA projections to the NAcc. Recent findings from human brain imaging studies suggest that addiction is associated with alterations within the endorphin system and that the craving, distress, and dysphoria found in early alcohol and drug abstinence are associated with alterations in mOR (see section "Neuroimaging Studies in Addiction" below).

Emerging research also suggests that the kOR subtype may play a role in addiction, particularly the experience of negative emotional states during drug withdrawal (Bruijnzeel 2009). Stimulation of kOR inhibits dopamine release in the striatum, with chronic administration of drugs of abuse shown to increase the release of dynorphin in this region. This suggests that the chronic abuse of substances (not just opiates) may have an enduring effect at the kOR subtype.

Cannabinoids induce feelings of euphoria, disinhibition, relaxation, and analgesia (Curran et al. 2002). Delta-9-tetrahydrocannabinol (or THC) is the principal psychoactive constituent of cannabis and exerts its central effects via the cannabinoid 1 receptor (CB_1). CB_1 receptors are highly expressed in the cerebral cortex, hippocampus, striatum, amygdala, and cerebellum (Herkenham et al. 1991; Tsou et al. 1998). CB_1 receptors are also located in the VTA and NAcc, where they modulate dopaminergic firing (D'Souza et al. 2008; Huestis et al. 2007; Hunault et al. 2008). The presence of the CB_1 receptor in the hippocampus is believed to underlie the effects of cannabinoids on memory.

Alcohol also induces euphoria, relaxation, and disinhibition, while reducing stress and anxiety (Koob 2004). The reinforcing effects of alcohol likely arise from its interaction with numerous neurotransmitter systems in the brain. Two key systems involved are opiate and GABA (the brain's major inhibitory neurotransmitter). Alcohol increases endogenous endorphin release and modulates $GABA_A$ and $GABA_B$ receptors to increase dopamine levels (Koob 2004; Sullivan et al. 2011; Tang et al. 2003). Stimulation of GABA results in anxiolysis and sedation, which are major drivers for alcohol abuse in humans (Sieghart 2006). Tolerance to alcohol involves adaptations in the GABA system as well as excitatory glutamatergic *N*-methyl-D-aspartate (NMDA) receptors, making the GABA system less responsive and increasing NDMA receptor activity. In the absence of alcohol, these adaptions lead to a hyperexcitable brain, resulting in signs and symptoms of alcohol withdrawal that include tremor, fits, and delirium tremens.

While tobacco use is not associated with significant psychological and social impairment typical of other types of addiction, it is the leading cause of preventable death in developed countries (Benowitz 2008; Mathers and Loncar 2006; Peto et al. 1996). Nicotine is the main addictive component in cigarettes (Benowitz 2009; Gray et al. 1996; Mansvelder and McGehee 2002) and acts on nicotinic acetylcholine receptors (nAChRs) in the brain, including those in the VTA, that modulate dopaminergic cell firing (Grady et al. 2010; Klink et al. 2001; Wooltorton et al. 2003; Drenan et al. 2010; Mameli-Engvall et al. 2006). The high-affinity $\alpha4\beta2$ subunit of the nAChR appears to be crucial to the positive-reinforcing and cognitive-enhancing effects of nicotine (Lippiello et al. 2006; Patterson et al. 2009).

Positron emission tomography (PET) studies in humans have demonstrated that smoking produces dopamine release in the VS (Brody et al. 2004). Furthermore, research in humans, investigating the effects of smoking on α4β2 nAChRs, has shown that smoking a full cigarette results in more than 88 % α4β2 subunit receptor occupancy, an effect which is accompanied by a significant reduction in cigarette craving (Brody et al. 2006). These PET research findings corroborate the value of medications that specifically target the α4β2 subunit of nAChRs (Gonzales et al. 2006; Jorenby et al. 2006) in reducing relapse in smokers attempting to quit.

Psychostimulants, such as cocaine and amphetamines, directly increase the concentration of dopamine in mesocorticolimbic brain regions (Kuhar et al. 1991; Wise 1996). Cocaine is a reuptake inhibitor that binds to the presynaptic dopamine transporter (DAT) (Amara and Kuhar 1993; Woolverton and Johnson 1992) that moves dopamine from the synapse back into presynaptic nerve terminals. By blocking the DAT, cocaine inhibits the reuptake of dopamine, increasing dopaminergic levels and amplifying its reinforcing effects. Amphetamines also block the DAT but directly trigger dopamine release as well (Rudnick and Clark 1993). The increase in dopamine produced by psychostimulants correlates with the resulting "high" that people experience (Volkow et al. 1999). While the pharmacological effects of psychostimulants also increase levels of serotonin and norepinephrine in the brain (Howell and Kimmel 2008; Rudnick and Clark 1993; Sora et al. 2009), it is primarily their effects on dopamine at the NAcc that underlie their abuse potential. Ecstasy or MDMA, another amphetamine-type drug, primarily targets the serotonergic system by blocking serotonin reuptake, producing a different set of euphoric experiences.

Animal Models of Addiction

There are a variety of increasingly sophisticated animal models that have provided invaluable insights into both the neurobiology of addiction and the pharmacological actions of drugs of abuse (Feltenstein and See 2008; Heidbreder 2011; Yahyavi-Firouz-Abadi and See 2009). Models that have particularly served to elucidate important neurobehavioral mechanisms in addiction include intracranial self-stimulation (ICSS), conditioned place preference (CPP), behavioral sensitization, and self-administration paradigms. Furthermore, these models, particularly those involving self-administration, have also proved beneficial in examining the neurobiology and neuropharmacology of drug relapse.

Knowledge about brain regions important for reward originally began with research in rodents by Olds and Milner, who found that rats would expend a great deal of effort to electrically stimulate areas of the brain that form part of a reward circuit (Olds and Milner 1954). Additional evidence suggested that the rewarding effects of ICSS activated a dopamine projection from the VTA to the NAcc, via a pathway known as the medial forebrain bundle (Heimer and Van Hoesen 2006; Wise 2005). Drugs of abuse have been observed to decrease ICSS thresholds; that

is, the reinforcing properties of addictive drugs reduce the amount of brain stimulation required by the animal. Animal research has also revealed that the more addictive a substance is, the greater its ability to reduce the ICSS threshold. This model can be used to evaluate the abuse potential of different drugs. The ICSS model has also served as a unique experimental tool to assess alterations in the basal hedonic state of an animal following chronic drug exposure. In contrast, withdrawal from all major drugs of abuse produces an *increase* in ICSS thresholds; that is, the effects of drug withdrawal on reward circuitry increase the amount of brain stimulation required by the animal to overcome this state.

The CPP model utilizes the classical (Pavlovian) conditioning paradigm in which an animal learns associations between a conditioned stimulus (CS) and unconditioned stimulus (UCS). A CS (e.g., neutral object) is repeatedly paired with an UCS (e.g., drug), until the CS on its own comes to elicit the same response as the UCS. In the CPP model, an animal is exposed to an apparatus consisting of two neutral environments. These environments can differ in terms of a number of stimulus modalities, including color, texture, odor, and lighting (Bardo and Bevins 2000). One environment is paired with drug administration (CS+), while the other is paired with the administration of a control substance, usually saline (CS-). After a number of conditioning sessions, the animal (now in a drug-free state) is permitted free access to the environments of the apparatus, during which their preference for the two environments is measured (e.g., by frequency of entry into and the time spent in the environments). In accordance with the principles of classical conditioning, because the drug condition has reinforcing effects, the animal shows a significant preference for the drug-paired (CS+), over the saline-paired (CS−), environment.

Experimental studies show that various drugs of abuse (e.g., amphetamines, cocaine, heroin, nicotine) typically induce CPP for the drug-paired environment (Pastor et al. 2012; Sticht et al. 2010; Thorn et al. 2012), suggesting a role for classical conditioning in the acquisition of drug use behavior. The CPP model, however, possesses a number of limitations, including the method of drug administration (e.g., experimenter administered) that fails to model human drug use (i.e., self-administration), the potential confound of novelty on the day of testing, difficulties in generating dose–response curves, and the model being limited to use in rodents.

Behavioral sensitization involves a progressive increase in the motor stimulatory effects of a drug with repeated and intermittent administration. The development of behavioral sensitization has been hypothesized to represent the shift from drug "liking" to drug "wanting" that has been hypothesized to underlie compulsive drug use in humans (Berridge 2009; Berridge and Robinson 1998; Berridge et al. 2009; Robinson and Berridge 2000). The phenomenon of behavioral sensitization has been demonstrated for a variety of drugs of addiction, such as amphetamines (Degoulet et al. 2009), cocaine (Burger and Martin-Iverson 1994), and nicotine (Kosowski and Liljequist 2005). It may potentially model elements of drug craving and relapse in humans (Vanderschuren and Kalivas 2000). Although useful for studying several aspects of drug-induced neuroplasticity, the behavioral

sensitization model, like CPP, is limited because animals never experience contingent drug self-administration, a hallmark of human addiction.

The most widely accepted animal model of drug abuse and addiction is the self-administration paradigm. During this operant conditioning procedure, the animal presses a lever (i.e., the operandum), which triggers the delivery of a reward (e.g., cocaine). Animals can be trained to perform a variety of different operant behaviors (e.g., nose pokes) in order to receive the drug after varying amounts of attempts. Like humans, animals will readily make operant responses in order to self-administer most drugs of abuse, including opiates, cannabinoids, alcohol, nicotine, amphetamines, and cocaine (Feltenstein and See 2008; Heidbreder 2011; Yahyavi-Firouz-Abadi and See 2009). Furthermore, studies almost universally demonstrate that animals will preferentially respond on a reinforced (i.e., active), rather than a non-reinforced (i.e., inactive) operandum. This suggests that like humans, animals are able to rapidly discriminate between responses that elicit the delivery of drug and nondrug rewards.

While a variety of species and routes of drug administration can be used, most animal studies of addiction involve the use of rodents or nonhuman primates. Drugs of abuse are typically self-administered intravenously, via a chronic indwelling catheter, or orally. The abuse potential of different compounds in humans is well predicted by animal intravenous self-administration models. This suggests that this paradigm mimics human abuse with greater ecological validity than repeated experimenter-delivered administration (e.g., intraperitoneal, subcutaneous). Therefore, the drug self-administration model appears to possess reasonable face, construct. and predictive validity for examining the neuropharmacological profiles of drugs that are readily abused by humans.

Craving and the recommencement of drug seeking and drug taking following drug abstinence are significant features of addiction (Sinha and Li 2007; Volkow et al. 2002a, 2006b). Factors believed to contribute to drug craving and relapse include exposure to conditioned drug cues, negative mood states, and stress. These triggers have been examined using animal models of relapse that employ an "extinction–reinstatement" approach. In the "extinction–reinstatement model," animals are allowed to self-administer a drug (e.g., cocaine) for prolonged periods of time, mimicking chronic drug use in humans. The animals then undergo extinction training in which the previously reinforced behavior (e.g., pressing a lever) fails to elicit drug delivery. These animals are then exposed to small amounts of the previously administered drug (called drug priming) or environmental stressors (e.g., foot shock) to test the reinstatement of drug self-administration after extinction. Research has shown that conditioned cues, drug priming, and stress are all powerful triggers for the reinstatement of drug-seeking behavior, as indexed by an increase in a behavior previously paired with a drug (Shaham et al. 2003). The reinstatement of drug self-administration is believed to model relapse to drug use in humans. The application of the reinstatement model has also proved useful in examining the neural circuitry underlying drug relapse (Kruzich et al. 2001; Kruzich and See 2001; Weiss et al. 2000).

Neuroimaging Studies in Addiction

Studies Using Positron Emission Tomography (PET)

PET imaging directly assesses neurotransmitter systems in the brain by using a radioactive tracer that recognizes a particular target. There are a number of well characterized tracers for some neurotransmitter systems of interest in addiction (e.g., dopaminergic system), but not for others (e.g., glutamate). This limits the utility of PET investigations.

Dopamine

Cocaine and methamphetamine (or "crystal meth") increase dopamine levels in ways that can be measured by an increase in the displacement of PET tracers that bind to dopamine ($D_{2)}$ receptors (e.g., [^{11}C]raclopride). The increase in dopamine produced by stimulants in healthy volunteers is dose-related and reflects the "high" that people experience (Volkow et al. 1999). These findings, supported by earlier animal studies, showed that drugs of addiction increase dopamine in the NAcc. This led to the view that dopamine release was a necessary, perhaps even sufficient condition, for drugs to have addictive potential. Recent work, however, has cast doubt on this. Heroin and other opioids, nicotine, and cannabis do not appear to produce detectable increases in dopamine (Bossong et al. 2009; Brody et al. 2004; Daglish et al. 2008; Stokes et al. 2009).

In cocaine- and alcohol-dependent individuals, amphetamine- or methylphenidate-stimulated release of dopamine, particularly in the ventral striatum, is blunted compared with healthy volunteers (Martinez et al. 2005). This finding challenges the theory of sensitization, which would predict increased dopamine levels in addicted individuals. Cocaine-dependent individuals also reported a reduced "high" and blunted change in dopamine levels that predicted the choice for cocaine over money (Martinez et al. 2007; Volkow et al. 1997).

The dopamine receptor, however, may play a key role in addiction propensity. Low levels of dopamine receptors are associated with a greater rewarding effect of stimulants (Volkow et al. 1999), while high levels are possibly protective in alcoholism (Volkow et al. 2006a). The use of stimulants (e.g., cocaine and methamphetamine) has been shown to lower dopamine receptor numbers (Dagher et al. 2001; Heinz et al. 2004; Lee et al. 2009; Volkow et al. 2001). Similarly, in alcohol dependence, lower striatal $D_{2/3}$ receptor availability has been reported (Volkow et al. 1996; Martinez et al. 2005). However, there is no evidence of reductions in $D_{2/3}$ receptor availability in cannabis dependence (Sevy et al. 2008) or use (Stokes et al. 2012). A recent study has shown that DAT availability is significantly reduced in the striatum of long-term cannabis users and cigarette smokers (Leroy et al. 2011), suggesting that disturbances in dopamine functioning is associated with chronic use. Daglish et al. 2008 were also unable to detect lower striatal $D_{2/3}$ receptor levels in methadone-maintained, opioid-addicted individuals. Martinez and colleagues did report a reduction in recently abstinent heroin-addicted individuals (Martinez et al. 2011), suggesting that the level of striatal $D_{2/3}$ receptors

may depend on whether opioid dependent individuals are free of or maintained on opioid drugs.

Opioid System

In cocaine addicted individuals, regional brain mOR levels remained elevated in the anterior frontal/cingulate cortex during 12 weeks of abstinence (Gorelick et al. 2005). These regions are strongly implicated in "top-down" cognitive regulation of impulses and behavior. Elevated mOR levels in the medial frontal and middle frontal gyri prior to psychosocial treatment were significantly associated with greater cocaine use during treatment (Ghitza et al. 2010). This study also found that elevations in mOR levels in the anterior cingulate cortex (ACC), medial frontal, and insular cortices correlated with a shorter duration of cocaine abstinence. Significantly, mOR binding was a more powerful predictor of treatment outcome than baseline drug and alcohol use.

The endogenous opioid system plays a significant role in alcohol dependence, as indicated by the efficacy of opiate antagonists (e.g., naltrexone) in pharmacotherapeutic trials (Lingford-Hughes et al. 2012a). Several studies have reported an increased availability of mOR in striatal regions in abstinent alcoholics (Heinz et al. 2005; Williams et al. 2009; Weerts et al. 2011). A similar increase in mOR availability has been found in abstinent opioid-dependent individuals (Williams et al. 2007). An increased availability of mOR has been demonstrated in addiction to a number of pharmacologically different substances of abuse and therefore may be involved in the vulnerability to and perpetuation of drug taking after abstinence.

GABA

Several studies have shown that GABA binding is lower in abstinent alcohol-dependent patients (Abi-Dargham et al. 1998; Lingford-Hughes et al. 1998) or its function reduced (Lingford-Hughes et al. 2005). The reduction in GABA binding may be the result of the downregulation of GABA in order to reduce the impact of sedative drugs on the GABA system. Individuals at risk of alcoholism, and addiction in general, may have preexisting reduced levels of GABA activity. The α_5 subtype of the $GABA_A$ receptor is highly expressed in brain regions that regulate emotion and reward, such as the ventral striatum, and a reduction in these receptors is found in persons with alcoholism (Lingford-Hughes et al. 2012b).

Studies Using Functional MRI (fMRI)

fMRI exploits the fact that the magnetic properties of blood change as oxygen is removed. These changes can be detected using an MRI measure known as the Blood-Oxygen-Level-Dependent (BOLD) signal while a person performs a behavioral task (e.g., reward learning). The BOLD response represents the change in oxyhemoglobin to deoxyhemoglobin ratio in venous blood. The strength of this signal in a brain region (e.g., ventral striatum) indicates the relative level of

oxygenated to deoxygenated blood at that location. Because neuronal activity requires oxygen, the BOLD signal is believed to indirectly reflect neuronal activity at that location during the psychological process being studied.

The use of behavioral assays that specifically tap into the neural circuitry on which drugs of abuse act allows fMRI neuroscientists to explore differences and similarities between the long-term effects of different drugs. The cognitive domains that have been under investigation in recent years, and which have provided some insight into the addicted brain, comprise memory, planning and impulse control, and more subjective experiences such as empathy (see below).

Drug-Related Stimuli

The production of strong emotional and cognitive responses to drug-related stimuli, referred to as cue reactivity, is a common and clinically important feature of drug addiction. Studies have investigated the neural correlates of cue reactivity and craving using cue-exposure techniques, which are ethically less challenging than giving drugs of abuse to addicted individuals. In particular the reactivity of neural reward circuits to drug-related cues has been widely studied to test whether there is an "overvaluation" of drug reinforcers, as has been hypothesized (Goldstein and Volkow 2002). Understanding how this system operates is important because drug-related cues may increase attentional bias and expectancy of drug delivery in both current and abstinent drug users. Such studies may potentially identify neural mechanisms and inform treatment development by providing potential cognitive or pharmacological targets (Muraven 2010; Schoenmakers et al. 2010; Shoptaw et al. 2008; Franklin et al. 2011; Goldstein et al. 2010).

fMRI studies have identified common brain regions (e.g., amygdala, OFC, and VS) that are involved in cue reactivity and craving elicited by drug-related cues in drug-using populations. We describe studies in nicotine addiction to illustrate how such imaging and reactivity has clinical relevance. Greater reactivity to smoking-related images has been reported in the insula and dorsal ACC (dACC) in those nicotine-dependent women who relapsed (Janes et al. 2010). The importance of the insula, which integrates interoceptive (i.e., bodily) states into conscious feelings and decision-making processes involving uncertain risk and reward, has recently emerged with evidence that damage to the insula disrupts nicotine addiction (Naqvi and Bechara 2008). Another study revealed that extinction-based smoking cessation treatment attenuated responses to smoking cues in the amygdala, and the same attenuation pattern in the thalamus predicted which smokers remained abstinent (McClernon et al. 2007). Concerning the impact of medication, varenicline has been shown to reduce responses in the VS and medial OFC to smoking-related cues as well as subjective craving (Franklin et al. 2011).

Imaging with alcohol-related cues has shown activation of similar brain areas. For instance, heavy drinkers show significantly greater activations in the dorsal striatum (DS) than social drinkers, and light drinkers show higher cue-induced activations in the VS and prefrontal areas than heavy social drinkers (Vollstadt-Klein et al. 2010). Detoxified alcoholics have less activation in the VS during the anticipation of nondrug rewards than healthy controls but increased VS activation

in response to alcohol-associated cues (Wrase et al. 2007). This finding suggests that mesolimbic activation in alcoholics (and addiction as a whole) is biased toward the processing of alcohol, as opposed to conventional reward cues, supporting the hypothesis of a reward deficiency syndrome. Various medications such as naltrexone (mOR antagonist), ondansetron (serotonin $5HT_3$ receptor antagonist), and aripiprazole ($D_{2/3}$ partial agonist) all reduce VS activation in response to alcohol-related cues in non-treatment-seeking alcoholics (Myrick et al. 2008, 2010).

In abstinent heroin addicts and cocaine abusers, salient drug-related cues have been shown to result in activation in the ACC in all participants, but PFC activation was only seen in those that experienced craving (Wexler et al. 2001). The study by Daglish et al. (2001) also revealed that ACC activation increased, rather than decreased, with the duration of abstinence. This finding may support the long-held belief that addiction can be an enduring process involving long-term adaptations in various circuits. It has been suggested that increased activity in the OFC reflects a hypersensitivity to reward (Bolla et al. 2003), whereas reduced activity in ACC reflects hyposensitivity to punishment (Garavan and Stout 2005).

As with medications to treat alcoholism, medications used to treat opiate addiction, such as methadone and buprenorphine, have been shown to reduce responses in the insula and hippocampus to salient drug cues (Langleben et al. 2008; Mei et al. 2010). It appears however that activity in the OFC does not dissipate after medication, the impact and clinical implications of which requires further study.

The development of a conditioned, cue-induced neural attentional bias in response to drug-predictive stimuli is accompanied by craving in different drug-using populations. This bias may be implicit in maintaining addictive behaviors and provoking drug relapse among users attempting to remain abstinent. Significantly, functional brain imaging procedures have been shown to reliably measure the effect of neural responses to drug-related stimuli on drug relapse. This may be important when testing the effects of medications on these responses. Future research may improve treatment outcomes in addiction medicine by identifying neural signatures that predict relapse.

Reward Processing

Reward is a central driver of incentive-based learning that elicits appropriate responses to stimuli and shapes the development of goal-directed behaviors. Motivational theories of drug use make different predictions about how drug use may differentially recruit brain areas, such as the VS, in response to rewards (Bjork et al. 2008). The reward deficiency syndrome (RDS) and the allostatic hypotheses (AH), for example, both postulate that addiction is the result of a deficit in dopamine motivational circuitry for nondrug rewards and that only drugs of abuse are able to normalize dopamine at the VS (Blum et al. 2000; Koob et al. 2004). This may induce reflexive, conditioned responses to drug cues and diminish responses to cues that signal nondrug rewards. Alternatively, the “impulsivity hypothesis” of addiction suggests that persons who are vulnerable to, or suffering from, addiction have an excessive approach and reduced inhibitory control over their behavior

(Bechara 2005; Bickel et al. 2007). This hypothesis is supported by longitudinal studies which have shown that both poor self-control and high novelty seeking in childhood are significant predictors of substance use in adolescence (Ding et al. 2004; Masse and Tremblay 1997; Myers et al. 1995) and addiction in later life (Fergusson et al. 2007).

Substance-dependent persons exhibit both impulsive and reward-centered choice behavior, and those with alcohol, cocaine, heroin, and nicotine dependence have an increased preference for small immediate over larger delayed rewards (Bechara et al. 2001; Bickel and Marsch 2001; Bjork et al. 2004; Heil et al. 2006; Reynolds and Fields 2011; Robles et al. 2011). This suggests that individuals who are both prone to, and engage in, chronic substance use have some combination of reward hypersensitivity and deficient inhibitory control (Bechara 2005; Bickel et al. 2007; Solomon and Corbit 1974). Assessing neural responses to nondrug rewards in substance abusers has particular value in evaluating these hypotheses and establishing patterns of reward functioning in addiction.

As described above, significantly lower numbers of D_2 receptors or released dopamine have been found in the striatum of people addicted to alcohol, cocaine, and methamphetamine (Martinez et al. 2005, 2007, 2009, 2011; Volkow et al. 2004). While this evidence is consistent with the RDS and AH, there is less consistent evidence in heroin, nicotine, or opioid addiction. It is not easy to determine whether the impairment precedes or follows addiction. Those at risk of initiating substance abuse may be hyporesponsive to nondrug rewards due to deficient dopamine functioning in the striatum which is overcome by taking drugs of abuse that enhance dopamine levels.

Most fMRI studies in addiction have attempted to examine reward sensitivity using the Monetary Incentive Delay (MID) task (Knutson et al. 2001). The MID task allows researchers to measure brain activation while a person anticipates and receives monetary reward and punishment. The person first views a brief visual cue indicating the type of reward trial they will participate in. This is followed by a short delay after which the person responds to a target stimulus and does or does not receive a reward depending on their response to the target. Significantly, fMRI BOLD responses during the MID delay period correlate with dopamine release in the VS (Schott et al. 2008), appearing to substantiate its sensitivity to dopamine reward functioning.

In alcoholism, support for the RDS/AH is demonstrated by blunted VS responses during reward anticipation compared with nonalcoholics (Beck et al. 2009; Wrase et al. 2007). However, alcoholics did not differ from nonalcoholics during reward anticipation, but they did differ in their responses to reward outcomes (Bjork et al. 2008), a finding more consistent with the impulsivity hypothesis. In cannabis-using populations, there is support for both hypotheses. Greater activation in the VS has been shown in cannabis users than drug-naïve controls during reward anticipation, consistent with the impulsivity hypothesis (Nestor et al. 2010). By contrast, Van Hell and colleagues found that cannabis users had significantly less activation in the VS compared to non-cigarette smokers, but not cigarette smokers (van Hell et al. 2010), thereby supporting the RDS/AH.

Greater activation in the left and right VS, right caudate, and right insula has been shown in treatment-seeking cocaine-addicted individuals using the MID (Jia et al. 2011). Notably, some neural responses predicted treatment success with activation during reward anticipation in the bilateral thalamus and right caudate negatively associated with cocaine-negative urinalyses and activation in the left amygdala and parahippocampal gyrus correlated negatively with treatment retention. These findings suggest that in treatment-seeking cocaine-addicted persons, impulsive corticolimbic reward circuitry for nondrug rewards may be a neural biomarker that predicts treatment outcome (Jia et al. 2011). (Goldstein et al. 2007a) have also reported dysfunctional PFC activation during instrumental tasks in cocaine-addicted persons (Goldstein et al. 2007b). Finally, it has also been shown that in cigarette smokers, neural responses in the VS during reward anticipation are significantly lower than in control subjects (Peters et al. 2011). This has also been observed during the receipt of delayed rewards in this population (Luo et al. 2011).

The concepts of reward and impulsivity are both important in eliciting appropriate responses to stimuli and shaping the development of goal-directed behaviors. Since the empirical findings to date are consistent with both hypotheses, future research on the processing of nondrug rewards in addiction will need to address a potential disparity in neural responses in different types of addictions. In doing so, brain imaging research of reward processing in substance abusers may be able to delineate neural responses that are contingent upon the substance of abuse, the treatment-seeking status of the individual, and the duration of their abstinence.

Cognitive Control and Decision-Making

Flexible goal-directed behavior requires an adaptive cognitive control system for organizing and optimizing processing (Ridderinkhof et al. 2004a, b). Evidence from cognitive neuroscience is beginning to converge on the different contributions of the PFC in cognitive control. This convergence of evidence may identify potential biomarkers of compromised cognition that predict both the initiation and continuation of drug abuse. Since addiction is by definition continued drug use and recurrent drug relapse in the face of serious negative consequences, decrements in cognitive inhibitory control may be a core feature of the disease.

Laboratory tests of cognitive inhibitory control usually involve a person withholding a habitual motor response or ignoring the presentation of irrelevant stimuli while continually updating information and monitoring one's performance. The processes of cognitive inhibitory control and monitoring have consistently been shown to involve the PFC and ACC (Carter et al. 1998; Garavan et al. 1999, 2002; Ullsperger and von Cramon 2001). If the ability to inhibit and monitor one's behavior is important in the development and maintenance of addiction (Garavan and Stout 2005), then brain imaging assessments of cognitive inhibitory control may identify deficits in both behavior and brain functioning.

Dysfunctional activity in the PFC including ACC and OFC of different drug-using (i.e., alcohol, cannabis, cocaine, heroin, methamphetamine and nicotine) individuals has been shown in fMRI studies using tests of cognitive inhibitory control and monitoring when compared with demographically matched drug-naïve

individuals (Volkow et al. 2007; Garavan et al. 2008; Goldstein et al. 2004, 2010; Hester and Garavan 2004; Kaufman et al. 2003). Importantly, it has been shown that severe global cognitive impairment makes cocaine-addicted individuals less amenable to behavioral treatments (Aharonovich et al. 2003, 2006). This underscores the need to uncover biomarkers of cognitive control in addiction to inform rehabilitation programs for individual substance abusers.

Error monitoring has also been shown to be impaired in substance using populations, for example. Reduced functioning in the ACC when cannabis users are required to indicate their awareness of errors (Hester et al. 2009) or in chronic heroin users during error monitoring (Forman et al. 2004). Notably, previous research in early cocaine and methamphetamine abstinence has shown cortical neural deficits during verbal and visuospatial (Kubler et al. 2005) working memory (Moeller et al. 2010; Tomasi et al. 2007), conflict resolution (Nestor et al. 2011a) and decision-making processes (Hoffman et al. 2008; Monterosso et al. 2007). These findings support the notion that disruptions in prefrontal circuits are important for general, flexible, goal-directed behavior. Interestingly one study has shown that ex-smokers who had been abstinent for a year or more had increased lateral PFC activation compared with both smokers and nicotine naïve participants (Nestor et al. 2011b). Increased lateral PFC activation may be an important characteristic of successful abstinence in former smokers.

To assess decision-making in individuals with substance dependence, studies have used the Iowa Gambling Task (IGT) (Bechara et al. 1994). On this task patients with damage to the ventromedial prefrontal cortex (VMPFC) appear to be oblivious to the future consequences of their actions (i.e., myopia for the future), appearing only to be guided by their immediate prospects. Subsequent neuroimaging studies in healthy participants using the IGT have shown increased activation in the VMPFC, ACC, parietal/insular cortices, amygdala, and striatum during the actual decision-making component of the task (Ernst et al. 2002; Matthews et al. 2004; Verney et al. 2003). All of these regions are known to be affected by drugs of abuse. This had led to the “somatic-marker” hypothesis in which decision-making depends on the neural substrates that regulate homeostasis, emotion, and feeling (Verdejo-Garcia and Bechara 2009). According to this model, there should be a link between alterations in processing emotions in substance abusers and their impairments in decision-making.

There is some support for this hypothesis. For example, after 3 weeks abstinence, cocaine abusers have greater activation during performance of the IGT in the right OFC and less activation in the right DLPFC and left medial PFC than a control group (Bolla et al. 2003). These results suggest that cocaine abusers show persistent functional abnormalities in prefrontal neural networks involved in decision-making that may undermine attempts to remain abstinent. In a similar study, after 4 weeks of abstinence cannabis users, particularly heavy users (53–84 joints/week), had greater activation in the left cerebellum and less activation in the right OFC and DLPFC than controls (Bolla et al. 2005). These preliminary findings suggest that prefrontal neural deficits in heavy cannabis users are manifested in decrements in decision-making.

Other studies have examined patterns of regional brain activation in abstinent drug users during decision-making. Imaging patterns in methamphetamine abusing individuals performing the two-choice prediction task have shown decreased activation of the OFC, DLPFC, insular, and inferior parietal cortices (Paulus et al. 2003). These patterns of brain activation were strong predictors of relapse. Here activation patterns in the right insular, posterior cingulate, and temporal cortex obtained in early recovery correctly predicted 90 % of subjects who did not relapse and 94 % of subjects who did (Paulus et al. 2005).

Summary

Our knowledge about how drugs affect brain functioning and neural circuits in abuse and dependence has substantially increased in the last few decades due to developments in neuroimaging. Animal studies have improved in their complexity to better reflect what happens in man. In human and animal studies, the mesolimbic dopaminergic system has continued to receive much attention, and evidence suggests that hypofunctioning in this system is involved in vulnerability to drug liking for naïve users and also to relapse in addicted individuals. The role of other neurotransmitter systems is receiving more attention, and the importance of opioid and GABAergic systems, for instance, is recognized and has led to improvements in clinical treatment. Psychological constructs of behaviors such as reward processing, decision-making, and impulsivity have been widely studied in substance use and abuse with impairments generally described. Challenges for the future include using our knowledge and neuroimaging to bring psychological and pharmacological theories closer together so that the interplay between the impact of the drugs and/or their psychological or pharmacological treatment on underlying psychological processes is clearer.

Abstract

Brain imaging research in addiction promises to provide neurobiological and functional markers that may improve treatment of alcoholism and other types of drug addiction. More speculatively, it may also enable us to prevent addiction by intervening early with individuals who are identified as being at increased risk. In this chapter, we review the research findings on the use of neuroimaging to identify those at greater risk of developing addiction and to match addicted individuals to the treatments that are most likely to assist them toward abstinence. We then discuss the ethical and public policy issues that may arise from the clinical use of these technologies. We consider issues such as: (i) the commercialization of neuroimaging via direct-to-consumer marketing before the technology has been properly validated; (ii) the misuse of neuroimaging to discriminate against individuals at increased risk of developing addiction; (iii) the possible benefits and risks of "medicalizing" drug use and addiction, including possible effects on stigmatization of, and discrimination against, drug-dependent persons; and (iv) the possible misuse of neurobiological theories of addiction by those marketing alcohol and tobacco to undermine public health strategies that aim to reduce the population-level harms these substances cause. Finally, we examine arguments that evaluations of the future predictive utility of neuroimaging in the field of addiction will require substantial investments in health services research to evaluate the cost-effectiveness of this approach. Ethical assessments of the proposed applications of neuroimaging research should be an integral part of this health services research.

Introduction

Over the past several decades, research into the neural correlates of addiction has shown that specific brain circuits are differentially activated by addictive drugs and drug-related cues and that these patterns of activation differ between persons who are, and are not, addicted to drugs (Ersche and Robbins 2011; Parvaz et al. 2011). See ► Chap. 65, "Neuroscience Perspectives on Addiction: Overview" in this section. These findings raise the possibility that imaging brain anatomy and functional circuitry may have two types of predictive applications in the field of addiction: (1) predicting how addicted individuals will respond to different types of treatments for their addiction (Ho et al. 2010; Hutchison 2010; Reske and Paulus 2011; Singh and Rose 2009) and, more speculatively, (2) identifying deviant brain characteristics in childhood or adolescence that predict an individual's susceptibility to developing addiction, potentially enabling addiction to be prevented (e.g., Duka et al. 2011; Ersche et al. 2011; Loth et al. 2011; Schumann et al. 2010). In this chapter, we critically discuss the likelihood of these applications being realized. We also consider the social and ethical issues that may arise if these forms of prediction – which we term *neuroprediction* for short – do prove possible.

We first describe the type of neuroimaging biomarkers that are most likely to be used to predict addiction susceptibility or treatment outcomes. We then briefly review what may be gleaned from research on the predictive value of genomic information (Evans et al. 2011; Gartner et al. 2009; Hall et al. 2010) as many of the issues in genetic prediction and neuroprediction of disease risk are likely to be similar (Evans et al. 2011; Hall et al. 2010; Ioannidis et al. 2010). We then consider some of the issues that may arise if these potential applications of neuroimaging are realized and made commercially available before the evidence is available to support their validity. Many of these issues have also arisen in debates about the risks and benefits of medicalizing human behavior, an approach that is facilitated by the provision of neurobiological explanations of disapproved forms of human behavior such as drug use and addiction (Campbell 2012; Midanik 2006; Netherland 2011).

Potential Applications of Neuroprediction in Addiction

The most immediate applications of neuroimaging are likely to be the clinical matching of addiction treatment to specific addicted persons to optimize outcomes (Reske and Paulus 2011). Recent findings from longitudinal neuroimaging studies in dementia provide a possible model for the clinical use of imaging in addiction. The rate and pattern of change in brain size and connections between brain regions can better distinguish between patients with dementia and control participants than simple differences in these measures at baseline (Pievani et al. 2011). These patterns appear to reflect underlying pathological changes in brain tissue that can distinguish between persons with different subtypes of dementia and also identify non-symptomatic cases of dementia to allow for earlier intervention (Pievani et al. 2011; Seeley et al. 2009). In the case of addiction, functional neuroimaging might predict which individuals require additional treatment (e.g., depot medication, a drug vaccine, additional social support, targeted neurocognitive training) to reduce relapse (Gu et al. 2010; Sinha 2011; Sutherland et al. 2012). These methods may also be used in correctional settings (see ▶ Chap. 107, “Prediction of Antisocial Behavior”) to predict the likelihood that paroled prisoners will return to drug use after their release (Nadelhoffer et al. 2010). In this chapter, we concentrate on potential uses of neuroprediction in voluntary treatment settings to avoid the additional ethical challenges introduced by their use within the criminal justice system.

The use of neuroimaging to predict future addiction risk in young adults is a much more speculative possibility. The research required to enable such prediction (e.g., large-scale prospective and longitudinal follow-up studies spanning 10–20 years) has not been completed, although it is beginning (e.g., Cheetham et al. 2012; Schumann et al. 2010). The aims of this research are to: (i) identify persons at increased risk of developing addiction and (ii) provide preventive or early intervention programs to reduce this risk. Assuming that it proves feasible to do these things, “predictive neuroimaging” will raise many more ethical issues than neuroimaging for treatment matching. Specifically, prediction will need

to be accurate enough to minimize the harms to persons who are mistakenly identified as being at risk of developing a socially stigmatized disorder (false positives).

Risk prediction is ethically justified if there is an effective intervention that reduces the likelihood of a disorder, with minimal adverse consequences, in those at high risk (Ioannidis 2009). The expert consensus is that we do not have effective medical or behavioral interventions to prevent addiction in high-risk persons (Babor et al. 2010a; Carter and Hall 2012). In the absence of such interventions, risk prediction would expose high-risk individuals to potential stigmatization and discrimination without any therapeutic benefits that might justify this risk. Experience with genetic prediction of disease risk suggests that simply telling a person that he or she is at increased risk is unlikely to change their behavior in ways that will reduce the risk (e.g., by avoiding drug use in the case of addiction) (Marteau et al. 2010). It is also not clear whether risk information based on brain imaging will prove more persuasive in reducing risky behavior than simpler information that is already available to persons at risk, namely, a family history of alcohol or drug problems.

We assume that any future use of neuroprediction in the field of addiction will use actuarial, that is, the mechanical combination of statistical information about the risk for future outcomes often used by insurance and financial institutions, rather than relying solely on the clinical judgments made by medical experts. This is because the preponderance of evidence suggests that clinical judgments perform uniformly poorer at this type of prediction than actuarial methods (Dawes et al. 1989). In making these predictions, neuroimaging data is likely to be combined with personal history and clinical information in a standardized way (e.g., using statistical multivariate pattern recognition or "classification" algorithms) rather than the unstandardized and unaided clinical judgment of an individual clinician (Klöppel et al. 2012; Nadelhoffer et al. 2010). The practical utility of this approach will depend on demonstrating that there is a greater improvement in prediction when neuroimaging information is combined with other information rather than when it is used as a single predictor. Health services research will be required to decide whether neuroimaging improves on simpler methods of prediction and if it does, whether the size of the improvement is sufficient to justify the additional costs of using neuroimaging.

Cautionary Experiences from Genomics

Some neuroscientists have expressed optimism about the future utility of neuroimaging in predicting the risk profile and treatment outcomes for addiction and other psychiatric disorders (Loth et al. 2011; Schumann et al. 2010). For instance, they have suggested that functional brain imaging of children or adolescents while they perform certain cognitive tasks will identify those at increased risk of developing addiction if they use drugs during adolescence (e.g., because they have poorly functioning inhibitory control circuits and/or a highly responsive

reward system) (Volkow and Li 2005). It may well prove possible to use imaging biomarkers to make predictions about addiction risk at a *group level* but experiences with genomic prediction of disease risk suggest much more caution when making predictions about the future utility of neuroprediction *in individual cases*.

There were similar high hopes for the predictive use of genomic information in medicine at the time that human genome project was nearing completion (Collins 1999). In the case of addiction, the realization of this hope seemed justified by twin and adoption studies which suggested that genetic factors make a substantial contribution to addiction susceptibility (Agrawal et al. 2012; Bierut 2011). The major challenge for genomic prediction of addiction risk, and disease risk more generally (Hall et al. 2010), has been the failure to identify specific mutations that strongly predict individual addiction risk (Agrawal et al. 2012; Bierut 2011). Large-scale Genome Wide Association Studies (GWAS) and meta-analyses of GWAS have generally identified large numbers of alleles that only weakly predict disease risk (Agrawal et al. 2012; Evans et al. 2011; Swendsen and Le Moal 2011). These alleles also appear to predict an increased risk of developing one or more of a cluster of correlated externalizing behaviors, such as antisocial behavior, drug use, precocious sexual activity, and aggressive acts to others, rather than predicting the risks of specific types of addiction (Edwards et al. 2009). Even when information from risk alleles is actuarially combined, genetic prediction of addiction risks often does not improve on prediction using crude information on family history of addiction (Gartner et al. 2009). This outcome is not surprising given the ontological gap between nuclear DNA and the behavioral phenotype, the likelihood that environmental experiences change gene expression (epigenetics), the probable role played by gene–environment correlations, and the possible role of gene–gene and gene–environment interactions in addiction (Agrawal et al. 2012).

Genetic information seems more useful in predicting treatment response in addicted persons and thereby allowing individuals to be matched to the treatment that is most likely to be effective for them (e.g., Chen et al. 2012). There is some evidence, for example, that common alleles differentially predict treatment outcome in persons with nicotine, alcohol, and opioid dependence (Agrawal et al. 2012). If these results are replicated, health services research will be required to compare the cost-effectiveness of treatment matching using genetic data with simpler treatment matching strategies. The latter could include, for example, giving all patients the most effective treatment first and reserving more intensive treatment for those who fail at first-line treatments.

Challenges in Neuroprediction of Addiction Risk

Neuroprediction of addiction risk and treatment response will probably share some of the challenges faced by genomic risk prediction. It will also face additional challenges that arise from the cost and impracticality of routinely using neuroimaging.

First, neuroimaging research studies are at risk of repeating the experience of publication bias that affected early studies in disease genomics. "Promising results" found in small sample studies were more likely to be published than failures to find differences, raising hopes about prediction that were not borne out in subsequent attempts to replicate in studies using larger samples (Ioannidis 2012). For example, a meta-analysis of studies of brain volume abnormalities in persons with a variety of psychiatric disorders found that more statistically significant results were reported than should have been the case given the small study samples and the small average differences between cases and controls (Ioannidis 2011). This suggests that the literature on this topic has been biased by the selective publication of false positive results in small studies that overestimate effect sizes. More generally, meta-analyses of studies of potential biomarkers in medicine have typically found that estimates of effect sizes for consistently replicated findings *decrease* as the number of published studies increases (Ioannidis 2013).

Second, the current state of neuroimaging research resembles that of genomic research in the first years after completion of the first draft of the human genome. There has been an exponential growth in the generation of large volumes of neuroimaging data in the absence of any consensus among investigators on how to standardize neuroimaging methods, cognitive tasks, and methods of data analysis. This has led to the publication of findings that are often perplexing and difficult to understand. It will be some time before a consensus emerges on these issues that will enable the sort of progress that has occurred in genomics after the advent of GWAS using very large pooled samples from multiple case–control studies, standardized genomic methods, and appropriate statistical methods to address serious multiple comparison problems.

Third, neuroimaging does have a major disadvantage compared to genotyping. Large-scale genotyping studies are relatively inexpensive and easier to conduct than the large-scale longitudinal neuroimaging studies that are required to test the predictive utility of neurobiological markers of addiction risk (e.g., the IMAGEN studies of Whelan et al. 2012). The cost of performing functional magnetic resonance imaging (fMRI) and positron emission topography (PET) scans are also unlikely to decline as quickly as the costs of genome scans have done. Neuroimaging requires individuals to attend specialist imaging facilities to undergo neuroimaging. The neuroimaging procedure is much more complicated, time consuming, and costly than it is to take the blood or saliva samples that enable large numbers of subjects to be genotyped cheaply using fast-throughput, next-generation genomic sequencing. Neuroimaging often measures changes in brain activity in response to behavioral or cognitive tasks that can be difficult to administer in uncooperative participants.

Fourth, it seems most likely that neuroimaging will have utility in clinical settings when matching addicted individuals to customized treatments (Reske and Paulus 2011). For instance, Paulus and colleagues (2005) showed that brain activation patterns obtained using fMRI were able to predict relapse in persons with methamphetamine dependence. Schutz (2008) has also reported that neuroimaging findings predict relapse risk in smokers. If these results are

replicated, we will need to see whether they also predict treatment outcome in other forms of drug dependence.

Fifth, the cost and logistical challenges of neuroimaging will be a barrier to its routine use in addiction treatment matching, even if matching proves possible in research studies. Large-scale neuroimaging will be practicable in tertiary research and treatment settings but primary care physicians will not be able to use these technologies or receive imaging results in a timely way from specialist imaging facilities. It seems more likely that treatment matching will be done using neuropsychological or behavioral tests that neuroimaging studies have shown to measure functioning in key brain regions (e.g., those that are associated with impulsive behavior and relapse to drug use or other compulsive behaviors) (e.g., Fontenelle et al. 2011; Goudriaan et al. 2008). This could include, for example, tests of attentional bias toward drug cues, impulsivity, and the inability to delay reward. These tests would be less expensive, and if they had equal or similar efficacy, would be more cost-effective than neuroimaging in predicting treatment outcome (Cox et al. 2002; Goudriaan et al. 2008; Paulus et al. 2005). Health services research will be required to establish the clinical and scientific validity of neurocognitive tests before they could be routinely used in clinical practice.

In order to assess the clinical utility of neuroimaging in addiction treatment matching, evidence will be needed to show that: (1) these methods predict different responses to various treatments for drug dependence (e.g., different drug treatments or psychological therapies) and (2) matching patients to treatments using this information is more cost-effective than giving everyone the treatment that is the most effective on average (i.e., regardless of genotype or neuroimaging results) (Hall 2007). In order to be cost-effective, these instruments will need to reliably predict differential treatment responses that are large enough to justify the additional costs of testing.

These evaluations will also need to assess the effects that this information has on addicted persons' beliefs about their ability to abstain from drug use. Studies suggest that smokers interpret genetic risk information to mean that they can only quit using biological interventions, if they are able to quit at all (Cappella et al. 2005; Wright et al. 2003). In these studies, smokers who accepted that genetic factors contributed to their cigarette smoking were less confident about quitting and more likely to believe that they needed a biological intervention to quit. Researchers will also need to assess whether neuroimaging information discourages quit attempts in those who try and fail to quit. Patients arguably have a right to be told about genetic risks information but providing this needs to be done in a way so as to avoid discouraging further quitting attempts because most addicted persons only achieve lasting abstinence after a number of attempts to quit (John et al. 2004).

Prediction of Addiction Risk

We do not have research evidence on whether neuroimaging in adolescence can predict addiction risk in young adulthood and we are unlikely to have such information

for some time. For the moment this use of neuroprediction is speculative. Nonetheless, there are some research findings that suggest that this may prove possible.

Longitudinal studies suggest that it is possible to predict the risk of addictive disorders in adulthood from characteristics measured in childhood and adolescence. Moffitt et al. (2011), for example, found that indicators of poor self-control in early childhood and adolescence predicted an increased risk of substance use disorders and poorer health, lower wealth, and an increased risk of police arrest in adulthood. Moffitt and colleagues measured impulsivity, conscientiousness, self-regulation, delay of gratification, inattention, hyperactivity, executive function, will power, and inter-temporal choice starting at the age of 3 and throughout childhood and adolescence in a birth cohort of 1,000 New Zealanders. Their study had a retention rate of over 90 % and there was very little selective attrition of those with lower self-control. The study also collected rich data on study participants and their families from infancy to adulthood. Participant self-control was assessed by measures of impulsive behavior (e.g., impulsive aggression, lack of persistence, and hyperactivity) that were collected at 3, 5, 7, 9, and 11 years of age. These included: researcher observations of behavior at age 3, teacher and parent ratings of behavior during childhood, and participants' self-reports of their behavior during adolescence and early adulthood. The study assessed the relationships between these measures and indicators of health, wealth, and criminal history at the age of 32.

Poor self-control that persisted throughout childhood and adolescence predicted poorer physical and mental health, lower wealth, and a higher risk of having been convicted of a criminal offence by age 32. Alcohol, tobacco, and cannabis use disorders occurred more often among those who were more impulsive in childhood and adolescence. On all these outcomes, the risks of poorer adult outcomes increased steeply as indicators of self-control declined. These relationships persisted after controlling for IQ and higher socioeconomic status, both of which were correlated with poorer self-control in childhood and with poorer adult outcomes.

These findings were supported by more detailed analyses of the data. Study participants whose self-control improved between childhood and young adulthood had better outcomes at age 32 than participants whose self-control did not improve in adulthood. Similarly, individuals with poor self-control in childhood who avoided adolescent "snares" (e.g., starting to smoke cigarettes, leaving school early, and adolescent pregnancy) did better than peers with poor self-control who did not avoid these snares. In fact, even behavioral ratings of self-control made by researchers at age 3 predicted poorer adult outcomes at age 32, although this prediction was poorer than in young people who showed persistent poor self-control throughout childhood and adolescence.

Neuroimaging research has suggested a possible neurobiological basis for the differences in impulsivity found by Moffitt et al. Ersche et al. (2012), for example, reported similar deficits in the neural tracts involved in impulsivity in non-substance-using individuals and their stimulant-dependent sibling. The brain scans of both sibling groups differed from a control group of unrelated healthy individuals who were matched for age and intelligence. The sibling pairs also showed larger deficits in

behavioral regulation than controls on the stop-signal task, a commonly used measure of inhibitory control. The authors argued that stimulant-abusing individuals have structural differences in the striatum and frontal cortices, brain regions that are associated with impaired behavioral control, making them more likely to abuse stimulant drugs. The fact that siblings with the same differences did not abuse stimulants indicates that other factors were also important. A correlation between the extent of impaired brain structure and the duration of stimulant drug use suggested that chronic stimulant abuse can produce these changes in brain structure.

A recent fMRI study has also found an association between self-reported adolescent drug use and patterns of activation in several cortical and subcortical neural networks involved in the inhibition of behavior, including regions implicated in impulsivity (e.g., the basal ganglia, pre-supplementary motor area, orbitofrontal cortices) (Whelan et al. 2012). In this study, the brains of 1,896 adolescents were imaged using fMRI while they performed a stop-signal task to identify the main brain regions involved in inhibitory control. Activation of this inhibitory network was correlated with self-reported alcohol, tobacco, and illicit drug use. This indicated that hypofunctioning in an orbitofrontal network was associated with the initiation of drug use, while right inferior frontal activity was related to the speed of the inhibition process and the use of illegal drugs.

These early results raise the possibility that neuroprediction of addiction risk may one day be possible. More authoritative assessments of the feasibility of neuroprediction require larger, prospective studies like that of the IMAGEN study that is currently following a cohort of 2,000 European adolescents. Participants have already undergone functional and structural neuroimaging studies in early adolescence and will be followed into adulthood. This type of study is required to decide whether differences in brain structure and function are causes or consequences of addiction. If brain function differs in adolescence between those who do and do not develop an addiction, then further studies will need to assess: whether these differences are large enough to reliably predict individual addiction risk; whether neuroprediction improves upon prediction using behavioral and self-report data, such as that collected in the study by Moffitt and colleagues (2011); and whether any improvements in prediction is sufficient to justify the cost of neuroimaging. Evaluations of the performance of neuroprediction will also need to attend to ethical issues that are raised by the prediction of a stigmatized form of behavior such as addiction (Garnett et al. 2011).

Ethical and Public Policy Implications

Premature Commercialization: Direct-to-Consumer Neuroimaging

Putative neuropredictive tests are already being marketed directly to consumers in private psychiatric treatment programs in the USA (Farah 2012). These practices parallel the direct to consumer (DTC) marketing of genetic tests that claim to predict disease risk even though these tests have not been clinically

validated (Mathews et al. 2012). In the USA, for example, the Amen Clinics (http://www.amenclinics.com/) have advertised directly to consumers that their neuroimaging provides novel diagnoses that predict the medical treatments to which individuals are most likely to respond. These clinics claim that tens of thousands of patients have undergone this type of neuroimaging (at their own expense) but present no evidence from the peer-reviewed literature to support the therapeutic claims made. The success of these forms of DTC neuroimaging will depend in large part on public misunderstandings of the information that neuroimaging provides.

Challenges for Public Understanding

Media representations of the role played by genetics in disease may be deterministic. While this may not be true for all media reports (Condit et al. 1998), some media reports claim that research has identified "the gene for addiction" (BBC News 2004; Doyle 2004), with the implication that people with this gene are very likely to develop addiction, and that those who do not have the gene are at low risk of doing so (Khoury et al. 2000). Public understandings of neuroimaging have been similarly simplified (see ▶ Chap. 92, "Neuroscience, Neuroethics, and the Media"), with newspaper articles claiming that neuroscientists have identified the "brain's addiction centre" (BBC News 2007). Misunderstandings of neuroimaging are arguably more likely due to: the novelty and complexity of the technology, the mysterious nature of the physical and biological processes that are measured, the close relationship between brain and behavior, and common misunderstandings of what brain images depict. Media stories on neuroimaging include multi-colored images of brain regions that are said to "light up" when people engage in a cognitive task or respond to drug-related stimuli (Racine et al. 2005, 2006). These are presented as if they were photographs of brain activity that enabled the content of individuals' brains to be directly read (Racine et al. 2005, 2006).

The journalists, and the public who read their articles, are unaware of the large amount of data processing that is required to produce these color-coded brain images (Illes and Racine 2005; Roskies 2008; Schleim and Roiser 2009). For example, it is not well understood that fMRI does not measure brain activation directly, but rather changes in blood oxygenation that occur a small time after brain areas have been activated. Nor is it understood that these changes reflect *relative* differences in activation (rather than absolute levels of brain activation) between different brain regions while a person performs two or more tasks (e.g., an experimental and a control task) (Bell and Racine 2009).

Neuroimages are produced by sophisticated statistical processing that requires numerous assumptions. The patterns of blood oxygenation produced are the product of statistical algorithms that highlight differences between regions in activation. The familiar multi-hued brain images are then produced by fitting *averages* of individual brain scans onto a standardized brain atlas and using arbitrary colors to indicate differences in level of activation between areas of the brain. The inferential

gap between brain activity and brain image is therefore much larger than that between a conventional photograph and its subject (Logothetis 2008; Schleim and Roiser 2009).

It is unclear to what extent the public perceives brain images as fixed, biological features of individuals. Neuroimaging research suggests a more plastic view in which brain images (whether functional or structural) can change fairly rapidly, contradicting the understandings of the brain as an organ with a limited capacity to regenerate and rewire. For example, numerous studies have demonstrated that exercise triggers the production of new neural cells (neurogenesis) (van Praag 2009). Brain imaging studies of London taxi drivers, who are required to memorize the large number of London street names and routes, showed that they develop much larger hippocampi – the regions of the brain responsible for memorizing factual knowledge – than matched controls (Maguire et al. 2000). Neuroimaging studies have also identified learning-related structural changes in the brain in: medical students studying for exams (Draganski et al. 2006), individuals experienced in meditating (Lazar et al. 2005), and persons learning new behaviors (Zatorre et al. 2012). This research suggests a more optimistic view about brain malleability and the potential for recovery from addiction, particularly if researchers can discern how to enhance these changes. This more optimistic view is now being communicated to the public in popular books about the "plastic brain" (e.g., Arrowsmith-Young 2012; Doidge 2007). The popularity of "brain training" games that claim to use neuroplasticity to prevent age-related cognitive decline suggests that the public may be receptive to this view.

We need to do more research on public understanding of neuroimaging and its policy implications. Some critics have argued that the public is overly persuaded by neuroimaging, and neuroscience research more generally (Nadelhoffer et al. 2010; Sinnott-Armstrong et al. 2008), in attaching too much significance to brain images and drawing erroneous inferences when presented with spurious neuroimaging results (Burge 2010; Quart 2012). More recent studies of the impact of neuroimages on mock juries suggest that the public may be more responsive to skeptical views of neuroimaging when such evidence is subject to cross-examination in mock courts (Schweitzer et al. 2011). A recent study has highlighted that it is not just the public that are swayed by neuroscientific explanations. Evidence presented to 180 US judges supporting a neurobiological explanation of a hypothetical psychopathic criminal act significantly reduced the severity of sentences (Aspinwall et al. 2012). It remains to be discovered whether better public education about neuroimaging technologies, and more informed media coverage, will reduce common misinterpretations and generate a more informed public, political representatives, and policy makers. This is an important area in need of good social and psychological research.

Benefits and Risks of Medicalizing Addictive Behavior

Neuroprediction fits well with the medicalization of human behavior, that is, a tendency to explain problematic human behavior in neurobiological terms and to

treat persons displaying these behaviors using drugs to intervene in their putatively disordered brain chemistry (Conrad 2007). Neurobiological explanations of addiction readily fit in with the idea that biological interventions, such as pharmacotherapies, are needed to treat addicted persons and possibly to prevent individuals who are at risk of addiction from developing it.

Any benefits to individuals that may flow from improved prediction of addiction risk presuppose that there are effective forms of prevention or early intervention available to reduce the likelihood that high-risk individuals will develop addiction. We do not have effective preventive interventions at this stage. Interventions such as educating young people about the harms of drug use have, at best, modest effects on their drug use, and not always for the better (Babor et al. 2010b). In the absence of effective preventive interventions, there is little benefit in identifying those who are at increased risk of developing addiction. In the absence of effective prevention, the neuroprediction of addiction risk raises many of the ethical and social concerns expressed by critics of the medicalization of other behavioral disorders (Rose 2006; Rose 2010).

Social scientists, sociologists, and ethicists (e.g., Ashcroft et al. 2007; Buchman et al. 2011; Choudhury et al. 2009; Netherland 2011; Press 2006; Verweij 1999) have argued that medicalization overemphasizes the biological origins of addictive (and other) socially disapproved behavior. Moreover, they argue, it does so at the expense of social and psychological explanations and it acts in ways that may adversely affect people who engage in these behaviors, or are perceived to be at risk of doing so (Caron et al. 2005). If addictions are seen as genetic and neurobiological disorders, for example, these critics argue more resources will be devoted to medical interventions and less attention to social policies, such as imposing higher taxes, banning promotions, and restricting access for young adults (Carlsten and Burke 2006; Chapman and MacKenzie 2010; Evans et al. 2011; Hall and Chikritzhs 2011; Merikangas and Risch 2003).

Critics also argue that neurobiological explanations may adversely affect addicted persons by, for example, reducing their confidence in their ability to quit smoking, drinking, or drug taking (Backlar 1996; Caron et al. 2005; Chapman and MacKenzie 2010). These critics also fear that increased acceptance of a neurobiological view will further stigmatize alcohol- and nicotine-dependent persons (Buchman et al. 2011; Caron et al. 2005). According to these critics, neuroimaging risk information could, like genetic risk information, lead to institutionalized discrimination by employers, who may decline to employ persons at increased addiction risk, and health and life insurers, who decline to cover those identified as being at increased risk of developing disease (Anderlik and Rothstein 2001; Geppert and Roberts 2005; Greely 2001; Hall and Rich 2000; Rothenberg et al. 1997). There is an extensive literature on these issues in the use of genetic prediction of disease risk (Heinrichs 2012; Rothstein and Anderlik 2001), but research is needed to assess to what extent ethical concerns about genetic testing also apply to the neuroprediction of addiction risk.

An argument has been made by Nadelhoffer et al. (2010) for using neuroprediction to improve prediction of re-offending in the criminal justice system. They argue that officials in the criminal justice system already make predictions about individuals, such as sentencing convicted offenders and deciding whether to release prisoners who have served part of their sentences. Moreover, many of these predictions are made using clinical judgment which we know is a very poor way of making decisions. Better predictions can be made using actuarial methods to combine information that includes neuroimaging data. They acknowledge the concerns about third-party uses of neuroimaging data but argue that these concerns are not peculiar to neuroprediction; the same issues arise whenever we attempt to predict risk.

A priority for future research on the utility of neuroprediction should be assessing the extent and the seriousness of the adverse effects of the medicalization that have been raised by social scientists. We need to know, for example, more about the severity of existing forms of stigmatization and their social effects on persons with addictive disorders. We also need to assess any adverse effects of stigma on persons who are identified as being at increased risk of addictive disorders (e.g., among parents or siblings). And we need to know more about the impact that neurobiological explanations of addiction have on addicted persons' interest in quitting and in their confidence in their ability to quit, should they make the attempt.

Subversive Policy Uses of Biological Risk Information

Critics of medicalization argue that neurobiological explanations of addictive behavior may replace effective population-based alcohol and tobacco strategies with high-risk strategies of intervention (Carlsten and Burke 2006; Merikangas and Risch 2003; Miller et al. 2012; Willett 2002). Population-based tobacco control strategies include taxing cigarettes and reducing opportunities to smoke, policies that have halved rates of smoking in Australia (White et al. 2003) and the USA (Pierce et al. 1998) over the past three decades. At present, it makes more policy sense to reduce cigarette smoking using these strategies than it does to spend scarce resources on identifying those at higher risk of becoming nicotine dependent or developing tobacco-related diseases, if they smoke tobacco (Hall et al. 2002; Khoury et al. 2004; Vos et al. 2010).

Public health professionals are concerned about the misuse of biological concepts of addiction risk by industries that want to promote tobacco use and harmful forms of alcohol use (Gundle et al. 2010; Miller et al. 2012). These industries have a history of using individual risk information to undermine public health policies that reduce the use of their products (Hall et al. 2008). Tobacco industry documents (Gundle et al. 2010), for example, show that the industry funded genetic research on smoking and tobacco-related disease in the 1970s and 1980s with the aim of locating the risks of smoking in the genome of the smoker

rather than in tobacco smoking (Gundle et al. 2010). The alcohol industry has also promoted the idea that alcohol-related problems are confined to a minority of genetically vulnerable drinkers (Hall 2005) and that these problems are best addressed by intervening with problem drinkers rather than public health measures that increase alcohol taxes and reduce the availability of alcohol (Babor et al. 2010b). The gambling industry has funded research into the neurobiology of problem gambling (Vrecko 2008), presumably for similar reasons, namely, to locate responsibility for the problem with affected individuals and shift policy attention away from regulating gambling (Schüll 2006).

None of these criticisms justify a ban on neuroimaging or other neurobiological research on any form of addiction, but caution against uncritically accepting the type of public policy implications that powerful economic interests will want to use this research to promote, namely, to locate the problem of addiction solely within the brains of affected individuals rather than modifying the type of social environments that promote the use of addictive commodities.

Conclusions

The failure to realize optimistic predictions about the genomic prediction of addiction risk should caution against similarly optimistic projections about the utility of neuroimaging in predicting addiction risk. Even if these methods prove able to predict individual addiction risk, the costs of screening large numbers of individuals in order to identify the small number at high risk is difficult to justify in the absence of effective preventive interventions. Population health strategies such as increased taxation and reduced opportunities to smoke or drink alcohol are likely to remain more efficient preventive strategies in reducing addiction to nicotine and alcohol.

Any future predictive use of neuroimaging information on addiction risk will need to address community concerns about privacy and the third-party use of such risk information. Public education is also needed about neuroimaging to reduce common misinterpretations of its findings. Research will also be needed on how best to present neuroimaging in ways that do not undermine successful public health strategies for reducing addiction and disease risk (McBride et al. 2010).

The most likely practical benefits of brain imaging in addiction will be in clinical settings. There, imaging may identify homogenous subtypes of addictive disorders that respond preferentially to different types of treatment. Evaluations of the utility of these applications of neuroimaging will require substantial investments in research to identify predictors of addiction treatment response. Assuming that these can be identified, health services research will then be required to evaluate their utility and cost-effectiveness. Such research should include analyses of the ethical issues that may be raised by future uses of neuroimaging.

Acknowledgments We would like to thank Ben Capps, Jayne Lucke, and Eric Racine for helpful comments on an earlier draft of this chapter.

Ethical Issues in the Treatment of Addiction 67

Benjamin Capps, Adrian Carter, and Yvette van der Eijk

Contents

Abstract

Addiction or dependence to a psychoactive substance – or drug – is a biopsychosocial disorder. Many aspects of addiction can be clinically treated, yet this raises some important ethical issues. The health and social problems resulting from addiction are generally influenced by sociopolitical agendas and

prevailing views about addiction, and therefore, we make some brief observations about how these affect the act, manner, or method of treating someone who is addicted.

In this chapter, we focus on some recent developments in the treatment of addiction: pharmacological approaches, and invasive brain therapies. In addition to giving an ethical overview of these, we look more generally at the justification for coerced treatment.

Introduction

This chapter considers the ethical aspects of certain treatments of addiction. Our focus is on psychoactive substances – more commonly known as drugs – that can produce an addictive pattern of use.

By addiction, we refer to a biopsychosocial disorder that is indicated by seemingly uncontrollable cravings for a particular substance (Engel 1980). The term “biopsychosocial” refers to the observation that substance dependence can result from (a combination of) various factors such as neurological adaptations, comorbid psychological disorders, or social circumstances. In this chapter, we will use “dependence” and “addiction” interchangeably to signify typical behavior associated with an addicted state. The American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders (American Psychiatric Association 1994) terms addiction as “substance dependence” and diagnoses it by three or more of the following criteria within a 12-month period: (1) tolerance; (2) withdrawal; (3) consuming more than intended; (4) persistent desire or unsuccessful effort to cut down; (5) spending a great deal of time with drug-related activity; (6) giving up important social, occupational, or recreational activities; and (7) continued consumption despite physical or psychological harm. While revisions of this definition are expected in DSM-V, due for release in 2013 (American Psychiatric Association 2012), defining such an intricate disorder has proved to be problematic. And yet such attempts underlie the ethical, political, and legal aspects of addicted states; the way in which it is perceived has important ethical implications for dependent individuals, those closely associated with them, and society as a whole.

The health and social problems resulting from addiction are generally influenced by sociopolitical agendas and the prevailing partisan and scientific understandings of addiction; such considerations might be scientifically informed, inclusive of current knowledge, or narrowly defined by prejudice or bias. How one thinks about addiction, therefore, will define the terms of the act, manner, or method of “treating” someone who is addicted. It is our intention to remain entirely neutral and non-prejudiced with respect to the terminologies “addict,” “person with addiction,” “drug user,” and similar definitions. Since our focus is on treatments, often we will also refer to the “patient.” Similarly, we refer to “drug use” to indicate the ingestion of a substance known to be associated with “addicted-like states” (*qua* “addictive drugs”). We avoid the

term “misuse” because this refers to the illegality (that may depend on jurisdiction) and essentially irresponsible ingestion of, and actions associated with, addictive drugs.

At opposing apexes are two prevailing models of dependence: the “moral choice” and the “medical” models. The moral choice model represents the conventional view in which individuals freely choose to engage in drug use. On this view, the ostensible state of neurological dependence is primarily used as an excuse for substance abuse. "Addictive behavior, therefore, is principally a deficit of the will (because of the choice to use – or not use drugs), and this justifies a punitive approach to hold such individuals responsible for misuse and any activities associated with it. Addicts may be subject to punishment and forced abstention, rather than voluntary therapy – a mainstay of traditional medical ethics. The medical model, on the other hand, while not excusing choice in all circumstances of drug use, does challenge assumptions about an addicted state: based on recent advances in neurobiological research, addiction can be viewed as a medical or more specifically, psychiatric condition that can be treated by evidence-based medical interventions. The medical model of addiction has led to the more specific chronic and relapsing brain-disease model of addiction (Koob and Le Moal 2006).

The aim of this chapter is not to take a stand on a specific ideology of addiction or approach to treatment but to discuss the ethical implications of implementing certain views in regard to interventions in addiction. Our approach has two prongs: one, to identify the relevant empirical literature that is used to ground opinion and policies in addiction treatment and two, to provide an introduction to some of the theoretical ideas that are supported by these observations. Admittedly, there will be gaps in our analysis, but our hope is that the reader will become aware of the current state of debate in addiction treatment. This involves understanding a complex interplay between the recognition of symptoms of dependence – whether biological and/or behavioral; attitudes to choices that lead to use, abuse, and misuse; experiences of harm caused by dependence; and partisan views of addiction, often swayed by political agendas, economics, and morals. Thus, the availability and means by which treatment is either offered or compelled is predicated by the view adopted. In this respect, we offer some suppositions in respect to the ethical issues in the following areas of addiction therapy: (1) the pharmacological treatment of drug addiction; (2) invasive therapies to reduce or treat addiction, such as deep brain stimulation and neurosurgery; and (3) more generally, the justification for coerced treatment.

The Pharmacological Treatment of Drug Addiction

To understand treatment approaches, one has to consider a number of factors: the availability and acceptance of evidence-based treatments, the wider causes of dependence (the clinical, or otherwise, diagnosis, including the social and biochemical triggers), and what constitutes successful – and the goals of – treatment. Much of the tension in treatment programs arises from

a difference between two broad approaches to drug dependence: (1) approaches that aim at achieving abstinence in the short to medium term and (2) harm minimization approaches which see abstinence as a long-term goal and aims in the short to medium term to encourage less harmful forms of drug use in the interests of reducing harm to users and the community. While these two approaches are sometimes characterized as mutually exclusive by some of their proponents, they are more accurately seen as lying on a continuum of treatment options. Many of the ethical issues in treatment of, for example, opioid dependence, arise from this difference in approach. How individuals align themselves within this debate is often driven by their understanding of the nature of dependence and by assumptions about the degree of autonomy and responsibility that individuals have over their conduct. In this first section, we comment on a wide spectrum of broadly pharmacological treatments.

Drug Substitution, Maintenance, and Relapse Treatments

Long-term pharmacological approaches to treating addiction can be understood as falling in to one of the two categories: (1) maintenance or substitution treatments that aim to reduce the harm caused by addiction by administering a safer drug that mimics the effect of the abused drug (referred to as an agonist) and (2) relapse prevention programs that aim to achieve and maintain abstinence following detoxification. Although this framework for understanding addiction treatment may not necessarily reflect the more varied, dynamic approaches in the clinical setting (see Carter and Hall 2012), treatment is premised on the grounds that it is possible to not only address the health of the patient but also control access to illegal substances and therefore minimize the potentially unlawful activities and the consequences associated with criminal (mis/ab)use.

In drug substitution or maintenance, a patient is prescribed an agonist that mimics the effects of the current drug of abuse but with a safer pharmacokinetic profile. Maintenance therapies are designed to stabilize the lives of individuals and reduce the harmful activities associated with their current drug use (e.g., overdose or comorbid disease), usually with the long-term aim of weaning individuals off addictive drugs altogether. One example is methadone, an opioid agonist that is legally taken (when it is prescribed) within a treatment program and has been effectively used as a substitution for heroin and morphine for almost five decades – principally by reducing cravings caused by drug abstention. Studies have also shown that treatment for heroin addiction, such as methadone maintenance therapy, results in decreased criminal and violent behavior (Ward et al. 1998). Nicotine replacement therapy (NRT) is an example of a maintenance therapy which aims to reduce the health-related harms of tobacco. Substitution drugs for psychostimulants and cannabis are currently being sought.

Relapse prevention often involves the prescription of a drug that blocks or attenuates the desired effects of the drug of abuse (e.g., Antabuse or disulfiram

for alcohol dependence or naltrexone for opioid dependence). The aim of relapse prevention treatments is to prevent a single use of a drug – a "slip" – leading to a relapse to chronic drug use.

Both approaches have been criticized on clinical grounds. For example, naltrexone is an opioid receptor antagonist used primarily in the treatment of alcohol or opioid dependence. It has been suggested that its long-term use may produce dysphoria and depressive symptoms (Dean et al. 2006) and attenuate the rewarding or hedonic effects of everyday "authentic" activities such as eating (Yeomans and Gray 2002), sex (Murphy et al. 1990), and physical exercise (Daniel et al. 1992). Agonists, such as methadone, are themselves addictive and can cause harms similar to those they are used to replace (e.g., overdose).

However, there is also often a moral refutation of such treatments, and which is preceded by a long history of moralizing about drug use, and policy and political attempts to curtail drug access because of social and other ostensible harms. This has led to a complex debate about the categorization of drugs in terms of opposing theories of liberty or freedom and moral conservatism; the latter of which can be used to label drug misuse as immoral. While unpacking these moral theories is beyond this chapter, one pertinent concern we can look briefly at is that these notional *treatment* strategies affect behavior in similar ways to illegally abused or misused drugs. (An issue here, but which we will have to leave unexplored, is whether a drug is categorized as illicit because of the harms it causes, its social acceptance, or some other artifact that has more dubious justification). So, even if in clinical terms these approaches can reduce the expected harm to the individual's health and intercedes in their drug-seeking activities, their application also contribute to the agent's loss of moral responsibility, and therefore, providing addicted individuals with addictive drugs (or with drugs with similar effects) is not treatment at all.

If one considers drug use to be morally contemptible because of the contemptuous effects it has on the individual, then it is unlikely that inducing similar effects for medical reasons is going to be ethically acceptable; the "excusive" reasoning used, it might be argued, becomes regressively circular. The solution is to denounce the causal factor of the dissipated will – drug misuse. So, in this respect, if goals and our realization of them are indications of our "sense of self" – and authentic behavior is part of our essential wellbeing – then offering alternative substances that merely perpetuate this deficit is just as ethically contentious. As some bioethicists have noted, all drugs that interfere with or undermine this sort of authentic action should be rebuked (Kass 2003). In this respect, some have opined that although less harm is expected by treating addiction by means of substitution or relapse prevention, they are still responsible for compromising the agent's will and thus do not stabilize this deficit. Moreover, "treating" addiction with another, albeit less harmful drug but which could also result in addiction, is speculatively not medically indicated (supposing that medicine's purpose is to make a patient well, then supplying potentially addictive drugs should be precluded).

In contrast, while the use of drugs by healthy adults to alter their sense of self may be an important neuro-ethical concern (Levy 2007), the situation is arguably very different in the case of addicted individuals who already have a distorted concept of

self – these individuals might be considered as *ill*. As such, addiction may significantly affect their will and resulting opportunities, and constrain the kind of life that is open to them: the illness produces significant emotional, physical, and psychological harms that limit their choices. A drug that is able to ameliorate these personal conditions could more correctly be seen as enabling, rather than impairing, the effected will.

In this brief analysis, one can clearly see how the construal of addiction – either as an undesired neurobiological manifestation or a personal (but disapprobational) choice – can influence treatment options and opportunities. On the one hand, if a person is considered to be taking drugs out of choice, then they do not have an impaired capacity to make decisions – therefore no treatment of this kind is warranted and stopping access to the drug altogether is a justified intervention. On the other hand, if they are medically unwell, then any means of recovery would be justified.

More generally, however, is a concern that a categorical rejection of the therapeutic use of any one of these approaches (for whatever reason) may lead to the sole use of another – sometimes the alternatives are less clinically effective, or, in the case of invasive operations on the brain (as we shall discuss below), less welcome. For example, the antagonist naltrexone may be used to treat opioid dependence at the expense of more effective treatments such as methadone and buprenorphine (agonists) – both which are prohibited in Russia (Krupitsky et al. 2010) and only offered in a limited manner in many other jurisdictions. Previous experience with substitute prescribing for nicotine dependence reveals a perverse regulatory standard that insists upon much tighter regulations for less harmful nicotine products, such as smokeless tobacco (e.g., snus), than are imposed on smoked tobacco products (Gartner et al. 2007). The reason for withholding some treatments is again an issue that is grounded in the historical and social context of drug use (Courtwright 2001). In a related example, a safe substitute for alcohol has been suggested in the form of a GABA partial-agonist that enjoys the social properties of alcohol without its biological toxicity (Nutt 2006). The idea, however, elicits the kinds of opinions that already call for regulatory obstacles to these “fringe” solutions and “engineered alternatives”; they only increase the range of recreational drugs available and the science does not address the “authenticity” concerns of drug misuse (or indeed the perceived social “harms” of recreational drug use). Such attitudes provide a major disincentive to pharmaceutical interest and political investment in harm reduction approaches. Although it is possible that safer recreational drugs will emerge as a by-product of basic pharmaceutical research, it is unlikely that there would be invested appropriate funds or that an effective political will would emerge for similar solutions to recreational drugs.

Long-Acting Treatment of Addiction: Immunological Blockade and Drug Implants

Researchers are seeking technological innovations to overcome the failure of addicted individuals to *comply* with pharmacological treatment by voluntarily

administering long-acting treatments. Although, as we shall discuss below, their coercive use may well signify an ambiguity with respect to choice and drug use – vaccines and other such substances may remove "choice" altogether. In respect to clinical use, long-acting treatments could be viewed in one of the two ways: (1) as a form of treatment that imposes a state of compliance (see our discussion on coercion in section "Coerced Addiction Treatment," below) or (2) a treatment that enables addicted individuals to adhere to their higher-order (and often presumed more authentic) desires to remain abstinent – a kind of "Ulyssian" contract to achieve abstinence despite "inauthentic" cravings that are part of their addiction. These treatments include long-acting interventions such as drug vaccines and drug implants, which, unlike oral treatments, cannot be easily circumvented or discontinued to allow individuals to regain the prior desired effects of drug use. Unlike traditional pharmacological treatments that require daily dosing, long-lasting treatments only need to be taken every 1–6 months (Harwood and Myers 2004).

"Vaccines" are a novel approach to tackling addiction. As prophylactics, they may prevent addiction by neutralizing a drug's rewarding effect in, for example, adolescents in their initial stages of drug use and experimentation. However, this application has failed to gain much traction for a number of reasons (e.g., Ashcroft et al. 2007). Vaccination could also be used as an addiction therapy to alleviate the effects of drug withdrawal and prevent possible relapse in persistent drug users. Although vaccines have been developed against methamphetamine, opioids, nicotine, cocaine, and phencyclidine (Orson et al. 2008), the majority of research has focussed on nicotine and cocaine.

The nicotine vaccine induces nicotine-specific antibodies that bind to the target drug preventing it from crossing the blood–brain barrier and acting on receptors in the brain (Nutt and Lingford-Hughes 2004). According to animal studies, drug vaccines reduce the amount of drug that reaches the brain and thereby can reduce the self-administration of the target drug. They are also highly specific and, because they do not cross the blood–brain barrier, produce no adverse effects on the central nervous system (Kosten and Owens 2005). This makes the nicotine vaccine an attractive alternative to drugs such as bupropion and varenicline, which have been associated with depression and suicidal ideation. Vaccination against nicotine could help abstinent smokers during the first few months after quitting when they are most vulnerable to relapse (Vocci and Chiang 2001).

So far, a number of phase II and III clinical trials for cocaine and nicotine vaccines have been reported (e.g., Maastricht University Medical Centre 2009; Martell et al. 2009). Only one-third of participants developed sufficient antibodies against the drug to prevent a relapse. Those individuals that developed the highest level of antibodies derived the most benefit from the intervention. Increasing the dosage is a possibility, but this could also increase the chance of potential side effects. A phase III clinical trial of the NicVax nicotine vaccine found it to be ineffective. New formulations of vaccines are currently in development that may provide greater immunoprotection against relapse (Moreno et al. 2010), but for now their practical utility remains elusive.

As an alternative to prophylactic vaccines, slow-release formulations are being developed. They typically come in the form of depot injections – oil suspensions that are injected into the muscle and drug implants – larger polymer-based implants inserted under the skin that slowly release the medication over weeks and months.

Researchers have focussed on the development of long-acting formulations of antagonist drugs that block or attenuate the use of addictive drugs. Several slow-release preparations of the antagonist naltrexone, used to treat alcohol and opioid dependence, have been developed (see Krupitsky and Blokhina 2010). The USA Food and Drug Administration approved the use of a naltrexone implant (Vivitrol) for the treatment of alcohol in 2006 and for opioid dependence in 2010. Slow-release agonists and partial agonists are also in development, although there is generally less eagerness to offer slow-release drugs closely related to those which are commonly abused. The exception is buprenorphine, a partial opioid agonist, of which several slow-release preparations were trialed for the treatment of opioid dependence (e.g., Ling et al. 2010). In this respect, a recent position statement by the Australian National Council on Drugs recommends that "given the very limited Australian data and evidence on the efficacy and safety of sustained release naltrexone preparations, their authorised use. . . is ethically problematic as it puts patients at risk of unknown harms, for an unknown benefit" (ANCD 2012, s. IX).

Although it remains to be seen whether blocking the rewarding effects of a particular drug is a clinically and socially acceptable way to reduce its use, these technologies also raise a number of ethical concerns in addition to questions over their efficacy. First, vaccines and sustained-release drugs may prove counterproductive if an individual attempts to overcome their blocking effects by increasing their drug dose. For example, one study for a cocaine vaccine found ten times more cocaine in the systems of their participants than researchers had encountered prior to the inoculation (Martell et al. 2009). Drugs such as nicotine and cocaine cause significant physical damage outside of their impact on the central nervous system (e.g., cardiovascular disease), and any increase in use has the potential to be harmful. Moreover, those who ambivalently agree to vaccination may also switch to using other possibly more dangerous drugs, more harmful routes of administration (e.g., intravenous injection), or much higher doses than usual, thus risking overdoses (Murray 2004); this was already seen in the cocaine vaccine trials just mentioned. It is also possible that readily available and effective vaccines could make experimentation with drugs seem less risky – that the possibility of addiction is not a concern for someone "vaccinated" – and therefore unwittingly increase drug use.

Second, the use of a vaccines or implants may also block the action of agonists or partial agonists (e.g., methadone and buprenorphine for opioid dependence). This would prevent the use of substitution therapies while vaccination remains effective and could raise concerns especially if drug substitution therapy turns out to be more effective. Vaccines and implants may also block the action of

medications used in the treatment of other medical conditions, such as opioid analgesics for pain relief (Ashcroft and Franey 2004).

Third, vaccines, implants, and other medical interventions could "medicalize" the socioeconomic problems that often drive drug use and addiction. Drug-based approaches tend to avoid the psychological characteristics underlying the addictive condition, such as compromised decision making and loss of opportunities, as well as comorbid conditions or the social conditions that may have led one into substance abuse in the first place. Vaccinating a school cohort because of fears of drug use does not deal with the circumstances of impecuniousness school environments or peer pressure, for example. A potentially more effective alternative for people in circumstances of social deprivation – a known factor in problematic drug use – is arguably a psychosocial approach, principally involving social interventions such community investment and the creation of opportunities.

Lastly, there are people that genuinely want to abstain from drug use but cannot control their cravings without medical help; for them, medical therapies, whether in the form of agonists, antagonists, or vaccines, should be made available on the basis of what is most effective. The challenge will be to identify those most likely to respond to different forms of treatment. Thus, it is important to neither medicalize nor trivialize addiction as a medically treatable disorder but to distinguish the individuals that would benefit from medical therapy from those who would not. This distinction will depend on neurobiological, as well as psychological and social factors. Thus, while novel therapies such as vaccines may find a place in the management of addiction, they are unlikely to benefit everyone. Addiction is a complex biopsychosocial disorder that deserves more than a "one-size-fits-all" approach. It is this observation that we carry through in the following sections.

Invasive Treatments of Addiction: Deep Brain Stimulation and Neurosurgery

The use of physical interventions to alter the suspected neurobiological centers of psychiatric disorders has an ignominious history. However, neuroscientific enthusiasm has seen a renewed interest in the use of these invasive techniques to treat intractable psychiatric conditions, including addiction (Carter and Hall 2012). The use of these treatments presupposes an illness rather than a mere deficit of will, although in more archaic times, one might have used such interventions to correct that deficit.

Neurosurgery

A novel and currently rarely used intervention for addiction is stereotactic ablative neurosurgery of brain structures thought to be involved in the condition.

Neurosurgery is an invasive and permanent intervention and is generally considered a treatment of last resort in cases of severe, treatment-resistant psychiatric disorders.

Russian and Chinese surgeons have used neurosurgical procedures to treat heroin addiction: 305 patients were reportedly operated on in Russia and over 500 in China. In China, stereotactic surgery was used to destroy the nucleus accumbens (NAc) (Gao et al. 2003), the brain region where rewarding effects of opioids and other drugs are thought to be mediated. Russian neurosurgeons lesioned the cingulate gyrus (CG) – a brain region that has previously been removed to treat obsessional disorders. International criticism prompted both countries to abandon the controversial treatment in 2003; but a recent report suggests that clinicians in China have commenced a clinical trial of neurosurgical treatment of opioid addiction and have trialed the same procedure in alcohol dependent individuals (Wu et al. 2010).

These reports raise a number of ethical concerns. Firstly, since there are effective nonsurgical treatments available for heroin addiction, such as methadone or buprenorphine, there ought to be important medical reasons to supersede established treatments with experimental neurosurgery. According to the clinical concept of *equipoise* – a principle which requires a genuine uncertainty in the medical community of the therapeutic merits of a treatment regimen – it is unethical to trial an invasive and experimental technology where effective and easily provided treatments are available. However, the reasons for not providing what are thought elsewhere to be effective treatments appears to be a sociopolitical and regulatory decision: methadone maintenance therapy was not made available in China at that time, and its use is prohibited by law in Russia.

Secondly, there are major concerns about the safety and efficacy of these neurosurgical procedures. Stereotactic neurosurgery is an invasive and irreversible procedure that involves drilling holes in the patient's skull and inserting electrodes into the brain to destroy the target region. Advocates of these procedures argue that they are less invasive and destructive than older forms of psychosurgery and report low rates of complications. However, these results come from uncontrolled studies that did not properly evaluate the cognitive and behavioral effects of destroying important neurological structures such as the NAc and aCG (Medvedev et al. 2003). Unknown extents of damage in turn leads to major concerns about the effects of producing irreversible lesions in neural centers that are implicated in the control of appetite, sexual behavior, and the formation of social bonds. At particular risk are permanent changes to the patient's responsiveness to reward their motivation and mood states, leading to clinical etiologies.

Finally, there are also doubts about whether patients have given free and informed consent because of the circumstances in which neurosurgery has been used. Chinese policies towards opioid dependence are largely punitive and retributive, with imprisonment and compulsory detoxification as first-line responses. In such circumstances, it is difficult to obtain free and informed consent without being coercive, especially given the drastic nature of neurosurgery and the lack of options for nonsurgical therapies (we talk more about this, below).

Deep Brain Stimulation

Deep brain stimulation (DBS) is a form of neurosurgery that has been proposed as a treatment of addiction (Krack et al. 2010). It involves inserting electrodes into specific brain regions to modulate neural activity via a battery-controlled external stimulator in the patient's chest and has been used to treat resistant cases of Parkinson's disease (PD) for almost three decades. It is also being trialed in intractable psychiatric conditions including Tourette's syndrome, obsessive-compulsive disorder (OCD), and depression (Krack et al. 2010).

DBS is often described as a reversible alternative to neurosurgery: it is nonetheless an invasive intervention that carries significant risks. Estimates of surgical complications vary markedly, largely due to differences in the competence of the teams performing the operation and variations in the procedure. A recent meta-analysis estimated that approximately 11 % of patients have adverse events from surgery (Krack et al. 2010). Estimates of major adverse surgical outcomes, such as intracerebral hemorrhages and death range from 0 % to 10 %, although in most centers, the prevalence of intracerebral hemorrhage is probably less than 2 %. The insertion of stimulating electrodes can also cause infections and produce cognitive, behavioral, or emotional disturbances and irreversible psychosocial harm. Given the risks associated with any neurosurgery, there needs to be a careful assessment of the risks and benefits of the procedure before DBS should be used to treat addiction.

So far, there have been several reports of the use of DBS in humans to treat addiction to nicotine, alcohol, and heroin (for a review, see Carter and Hall 2011). In one study, a woman was unsuccessfully treated for agoraphobia by bilateral DBS of the NAc but incidentally ameliorating her comorbid alcohol dependence. The same group reported smoking cessation in three of ten patients who underwent DBS of the NAc for Tourette's syndrome, OCD, or anxiety, but over two-thirds derived little benefit. A 47-year-old woman treated with DBS of the NAc for treatment-refractory OCD quit smoking and lost weight post-surgery. However, these changes emerged 10 months after her OCD symptoms disappeared, suggesting that this may have been an indirect effect of successful treatment of her OCD. Craving for alcohol and alcohol consumption were greatly reduced in three long-term, treatment refractory alcohol-dependent individuals who underwent DBS of the NAc; two were abstinent after 1 year and a third had markedly reduced their drinking. These were however small case studies with short-term follow-up and no comparison group (Carter and Hall 2011). The history of neurosurgical treatment in psychiatry cautions against uncritically accepting "positive results" from uncontrolled and often selectively reported clinical case series (Schlaepfer and Fins 2010).

Put together, the evidence to support trials of DBS in addiction is poor. The use of DBS in debilitating conditions such as PD is justified by the severity of the condition and the irreversible deterioration in motor function that characterizes the disease. Addiction, while often a serious condition, does not necessarily follow an inexorable path to severe disability and death; it is generally more amenable to pharmacological and psychotherapeutic treatment, and therefore drastic remedies

are less justifiable. Many cases of addiction treatment failure are due to inadequate access to well run and optimally provided forms of existing treatments (Carter and Hall 2012); a situation that would be exacerbated by an increased use of DBS to treat drug addiction. This suggests that the very uncertain benefits of DBS in alleviating the symptoms of addiction do not outweigh the known harms associated with the procedure or the harm of not providing DBS and relying upon currently available treatments provided to the highest standard.

There are other ethical and social issues that would need to be considered in evaluating the use of DBS for addiction. DBS is an extremely expensive procedure, costing about US $50,000 for the operation with US $10,000 ongoing maintenance costs every few years. This would utilize scarce health resources to treat a very small number of addicted patients with the income to pay for it, while failing to treat the majority. This raises a question of distributive justice, especially given the fact that many addicts are of low-income social groups. It may also negatively affect the provision of DBS to patients with illnesses that may benefit more from DBS, such as PD. The opportunity costs of providing DBS, even if it proved to be safe and effective, make such trials a low priority for public funding (Carter and Hall 2011).

One final, but important, consideration is that of patient expectations. Addicted individuals, as well as their loved ones, are often desperate to find a permanent cure and may have unreasonably high expectations based on uncritical media reports, as has happened with previous psychosurgical developments (Diefenbach et al. 1999). Therefore, the management of patient expectations about the limited and uncertain benefit of the treatment is an important challenge. It is important that the patients or their proxies understand that DBS, as well as neurosurgery, are invasive and risky procedures that do not necessarily offer a cure for addiction. Moreover, they cannot eliminate comorbid psychiatric issues or the social circumstances that led to drug use in the first place, and so patients may still require ongoing psychosocial support or social readjustment.

Coerced Addiction Treatment

Punitive Justifications for Coerced Addiction Treatments

One of the greatest challenges in addiction treatment is persuading individuals to enter and remain in treatment. Such individuals engage in risky behaviors that may be harmful to themselves and to others and in some cases also criminal. In many circumstances, these behaviors would appear to be directly related to their addiction. The person may consider themselves as unwell, but they are unable to seek out aid or sustain treatments. Or their condition may deteriorate despite their own efforts. Society may also want to reduce or limit the opportunities for these kinds of behavior and impose conditions and seek redress as a result of harmful acts as a result of drug use. The justification for coercion – to make somebody do something against his or her will by using force or threats – therefore features prominently in these treatment debates. Given the disputed nature of addiction and

the complex responses to it – including medical, social, legal, and political dimensions – we can only scratch the surface of this debate here.

Many countries have used some form of coercion to deliver addiction treatment. All of the treatments we have mentioned – drug substitution and relapse prevention, immunological blockade, and invasive brain manipulation – may be used under conditions of coercion. Coercion, here, falls under the conditions of forced choice in three interrelated aspects: compulsoriness (the person has limited option to refuse), desirableness (the choices offered are ones they would not normally make), and threat (failure to make or maintain a choice could be rebuked). The circumstances of coerced treatment become even more multifaceted when one factors in the possibility of compromised agency, such as situations when drug-using individuals are "out of it."

For our purposes, we can exclude the latter conditions because the person may often be treated in their "best interests" (or possibly supervised or restrained until able to consent) – at that time, they simply cannot signal their refusal to undergo treatment and therefore cannot be coerced in the same way as someone who is competent. We will also exclude the use of direct violence in situations of coercion because such obvious threats and actions (such that might be exercised on non-consenting prisoners) present no opportunity for consent. Such conditions are likely to be used within circumstances of incarceration and for tortuous or punishing affect and are only to be (controversially) justified if provocation of the legal system mandates such a response (and we have no intention here of raising further aspects of the jurisprudential conditions qualifying the punishment of drug users). We can also exclude deception, because such action is justified only by the toleration or acceptance of policies which permit the use of falsehood and misrepresentation to elicit a (fraudulent or misinformed) response or compliance. In coercive circumstances, then, the recipient gives his or her consent but is compelled in a way parallel to forced choice: actions under these conditions are not fully voluntary.

Coercion may be justified under either the moral or medical models of addiction. If coerced therapy leads to better outcomes for the addict *or* society, it may be justified on the grounds of paternalism (i.e., it elicits individual benefits to the patient even though those benefits might not be welcome) or public protection (i.e., purely societal benefits). This may be pivoted between the threat the addict imposes to himself or herself and society. However, if retribution is a priority, the moral choice model might be used to force unwanted interventions upon a convicted criminal on punitive grounds (in the sense that such interventions are not offered voluntarily because the convict might indulge "medicalized" excuses).

On the one hand, in failing to comply with the law (and in making that choice), the agent sacrifices their control over future circumstances so that an intervention can be compelled as part of rehabilitation or punishment. A person might also be offered a less punitive sanction if they agree to "treatment," but treatment is likely to be part of a vexed intention to deal with other harms such as HIV transmission. On the other hand, the medical model might use coercion as a veiled "best interest" justification so that nonconsensual treatment may be clinically justified or to offer alternatives as "the public interests," as in the case of drug courts where the

justification may be the benefits of rehabilitation rather than retribution. In the punitive setting, treatment may be offered as a *restrained* choice, i.e., an alternative to other sanctions. Such an approach has become commonplace in the USA with the emergence of Diversionary Drug Courts. Similar "progressive" programs were enthusiastically adopted by countries such as Australia, Canada, and the UK in the absence of strong empirical evidence demonstrating their efficacy (Carter and Hall 2012).

Not all jurisdictions operate the same; but basically, if the defendant qualifies for trial in one of these courts (depending on jurisdiction, type of offence, and the involvement of drug in committing the offence), and after an admitting plea, they may be given a suspended or some lesser sentence conditional on the successful completion of the treatment program. Courts can also impose a series of sanctions and can award privileges during that time. If the program is not completed successfully, the participant returns to court and may be resentenced. It is important to keep in perspective the types of offers made in coercive or semi-coercive situations. A patient is unlikely to be offered a *substantially* reduced sentence if they agree to treatment. Moreover, treatment as an alternative is only going to be offered in response to very minor crimes – possession, possibly some small-scale dealing or petty theft. Major crimes, for example, violence committed while intoxicated or linked to drug use, will generally be met with an expectation of retributive justice.

A concern is conflating medical roles (and the involvement of doctors) with those of the penal system; there are also further concerns regarding the effectiveness of coerced therapy in practice, and many of these concerns will depend and indeed transpire or not depending on the individual's perceptions of coercion, and their circumstances and appreciation of the situation. For example, if a person is forced into therapy, they may be more likely to resist treatment or become disparaging towards the medical fraternity (this is a particular concern with pregnant women). This can have significant impact on the individual and those around them and may not achieve treatment goals or exacerbate other clinical and social issues. The degree to which a program is "forced" upon individuals – at the extreme, using constraint – may negatively affect staff attitudes and compromise the treatment quality (Hall 1997). In other circumstances, an individual may be reluctant at first, but will engage and benefit from treatment eventually; in this case, the justification of coercion seems more defensible in terms of consequential utility measurements (that in the end, the individual and society are better off). Of course, the conception of benefit for the individual and the program administrators could well be very different. If a program is grounded in liberty or rights, then it seems that no degree of coercion would be justified in the case of a noncompetent patient.

There are different forms of coerced treatment for drug addiction that vary in the amount of force used (how voluntary the final decision might be) and the options offered and therefore, the degree to which they contravene an individual's freedom and what freedom they have rescinded because of felonious actions. Treatment may also be justified on the basis that the addict has impaired autonomy. This draws on the evidence addicts generally show strong signs of neurobiological change compared to nonaddicts (Leshner 1997; Hyman 2007; Kalant 2010;

Volkow et al. 2010). For example, Caplan (2008) argued that addicted individuals may be temporarily coerced into long-acting drug implant treatments on the grounds of "soft" paternalism – in their best interests – and that this would result in the long-term restoration of the person's autonomy. While, on the one hand, coercion is only as effective as it is applied, and ambivalence to treatment could indicate little intention for long-term abstinence, on the other hand, it is also possible that coerced treatment could restore autonomy – this is one of the arguments for the use of immunological blockade and drug implants approaches that force individuals to undergo a period of compelled abstinence for their own future benefit.

However, it is clear from studies that even those dependent on strongly addictive drugs, such as heroin and nicotine, have the ability to abstain, especially when given incentives. Social incentives, such as family pressure or threat of ending a relationship, are particularly effective (Hasin 1994). It is also clear that individuals generally have the competence to make decisions most of the time despite their drug use. Thus, while autonomy can be impaired in some individuals some of the time, it is not always compromised – for many it is at most perhaps lost temporally or intermittent; and this suggests that forced, or even compelled treatment, remains a human rights issue. Manifestations of brain illness, therefore, should not be taken to be catastrophic to present or future autonomy (Skog 2003). For example, millions of people are ostensibly addicted to nicotine, but that is insufficient grounds to assume they lack the same autonomy and rights as any other person, let alone justify coerced therapy on the basis that they are addicted.

One of the most persuasive arguments for the use of coercion in the treatment of addiction is that it lowers chances of reoffending because punitive-only measures fail to reduce drug use and drug-related crime (Hall 1997; Pedic 1990; Stathis 1991). There is also evidence that injecting drugs in prison increases the transmission of HIV and hepatitis C, suggesting that keeping drug users out of prison in favor of rehabilitation centers would protect them from contracting such diseases (Bell et al. 1992; Hubbard 1989; Ward et al. 1992). Of course, defendants may find the discomfort of a constrained choice more preferable to more serious and further sanctions. Here, the degree of choice becomes critical: because it is difficult to identify the motivation for acceding to treatment (because it is a coerced choice), then the validation of an addict's will become questionable, as do the circumstances that this creates for choices and options. Thus, the benefits of coerced therapy – in terms of a solution to the human and social blight of addiction – within a penal judicial system are debatable (especially if retribution is thought to be involved).

Others might find that the justification for treatment *or* punishment depends on whether the person is willing to commence therapy or not (i.e., willingly take action to stop their criminal activities) and which, in turn, compromises the case for coerced therapy. With already full prisons in some jurisdictions, encouraging individuals to take responsibility and deal with the circumstances which have lead to their (relatively minor) misdemeanors is preferable. In this respect, "treatment" may also be mandated with no other option – such as in "civil commitment programs" – where individuals are remanded into rehabilitation centers for

a minimum period of time. Here, other societal benefits become telling, such as recidivism and reducing the burden of disease. However, such programs are falling out of popularity since they are not as effective as "restrained choice" approaches (Wild et al. 2002).

Whether coercive treatment is ever appropriate remains a long-standing debate in regard to the rights of the individual, the protection of society from drug-associated harm, and the effectiveness of restrained and forced "choices." From whichever viewpoint, these considerations make the coercive use of treatments ethically contentious. At the very least, the safety and effectiveness of these technologies should be established in voluntary individuals before they are trialed in mandated situations.

Concluding Remarks

In this chapter, we have looked at conventional and experimental treatments for addiction. Our analysis proceeded along the lines that there are two predominant models of addiction – the moral and medical models. We conclude by stating that in isolation, both are potentially unhelpful in drug use policies, because, in different ways, they push reactions to compromising extremes. We conclude by offering an alternative to current, predominantly punitive responses to addiction and the neuroscience-based medical model.

Addiction appears to be a transient state and therefore is bereft of a straightforward solution. Punitive responses – the predominant model for current drug policies – are commonly criticized as aggravating by means of declaring a "war" on the circumstances and perpetuation of drug use. In this respect, some bioethicists have encouraged, perhaps unwittingly, the attitude that discouraging problematic drug use requires society to bring down the full force of retributive law upon individuals who flout drug prohibitions. This is a traditionally "hawkish" response to the drug misuse. The medical model, on the other hand, attempts to vindicate the "triumph" of neuroscience over addiction but at the same time can validate heroic and sometimes harsh or overly coercive treatment by the medical fraternity – a questionable role for them to assume. While this debate continues to create polemic camps, the loci of the addicted person have been lost; although they are quite possibly irresponsible and engaging in harmful actions, they could also be desperate for help to break the cycle of use. Perhaps most concerning is that contrary positions lose sight of the circumstances of drug use, which is often linked to conditions of poverty and social instability.

It is important, therefore, that neuroscience informs the addiction debate, that effective treatments – including social interventions and investment in providing opportunities – are considered together, and that whether medications are deployed or not is because they have been shown to reduce the relative harm of addiction, not because their psychopharmacological action is within a category that raises moral conflict, or will require laborious or rowdy political reform. Basing judgments on the premises of moralizing, rather than practical reasoning – that

includes the biological reality of addiction – could result in those who truly seek help being left untreated and diverted unnecessarily into penal systems. This has led to administering suboptimal, even harmful treatments, in order to avoid the use of effective alternative treatments. Effectively treating an individual for problematic drug use could conceivably, therefore, also include addressing social conditions of deprivation.

Throughout this chapter, we have emphasized that a one-size-fits-all approach is unlikely to result in comprehensive solutions to addiction. Perhaps a more fruitful approach would be to channel different people into appropriate treatment programs, which may or may not be linked to other punitive measures. Working out appropriate treatment, therefore, is a task of political will, available resources, and legal and social perceptions of drug use.

Drug Addiction and Criminal Responsibility

Contents

Abstract

Recent studies reveal some of the neurophysiological mechanisms involved in drug addiction. This prompts some theorists to claim that drug addiction diminishes responsibility. Stephen Morse however rejects this claim. Morse argues that these studies show that drug addiction involves neither compulsion, coercion, nor irrationality. He also adds that addicted people are responsible for becoming addicted and for failing to take measures to manage their addiction. After summarizing relevant neuroscience of addiction literature, this chapter engages critically with Morse to argue that a subgroup of addicted people does meet

plausible criteria for compulsion, coercion, or irrationality; that few addicted people are fully responsible for becoming addicted; and that some addicted people can be at least partly excused for failing to manage their addiction. Pickard and Lacey's "responsibility without blame" approach is also suggested as a fruitful basis for future work in this field.

Introduction

In recent years, neuroscientific studies have uncovered many of the physical processes and mechanisms involved in drug addiction and addiction-related behaviors. This evidence has prompted some theorists to claim that drug addicts cannot satisfy the conditions for criminal responsibility. If so, how does drug addiction impact on criminal responsibility? Are addicted criminal offenders fully responsible for what they do, or does their addiction somehow diminish their responsibility for the drug-related crimes that they commit?

Stephen Morse has defended the criminal law's commitment to holding people responsible for what they do from similar challenges posed by behavioral genetics and cognitive neuroscience. He has argued that once the conditions of criminal responsibility are properly understood, neuroscientific findings will not support the claim that drug addiction diminishes responsibility. On Morse's account, drug addiction has minimal impact on criminal responsibility because it does not involve compulsion, coercion, or irrationality and because addicted people are responsible for becoming addicted and for failing to take measures to manage their addiction once developed.

After summarizing the most salient points from the neuroscience of addiction literature for the present topic – see ▶ Chaps. 65, "Neuroscience Perspectives on Addiction: Overview" and ▶ 66, "Ethical Issues in the Neuroprediction of Addiction Risk and Treatment Response" of this handbook for in-depth discussion of the neuroscientific findings – this chapter engages more closely with Morse's arguments to reveal some of their weaknesses. It concludes that a subgroup of addicted people does meet plausible criteria for compulsion, coercion, or irrationality; that few addicted people are fully responsible for becoming addicted; and that some addicted people can be at least partly excused for failing to manage their addiction.

Drug Addiction and the Brain

Until relatively recently drug addiction was viewed in terms of pleasure seeking and pain avoidance. On this view, people's initial drug use is motivated by desire for pleasure produced by drugs (the drug-induced "high"). Drug tolerance is used to explain why over time increased doses are needed to produce the same pleasurable effects. The explanation offered for why some people do not stop using drugs even when pleasure decreases and the disadvantages of continued use are high – e.g., high financial costs of purchasing ever-increasing quantities of drugs, the drugs'

deleterious health effects, loss of control over use, the risk of a criminal conviction, or even death from overdose – is that they want to avoid unpleasant withdrawal symptoms as well as, to a lesser degree, continue seeking the pleasure experienced during initial drug use (Dalrymple 2006).

The virtue of this way of viewing drug addiction is its simplicity and intuitive plausibility – pleasure seeking and pain avoidance are offered to explain initial experimentation, continued use, and failure to terminate use when costs become high. However, apart from failing to provide a precise account of the mechanisms involved in drug addiction – i.e., what physical changes must occur in order for someone to become addicted to a drug – this account also does not provide a satisfying explanation of the apparent inexplicability of continued drug use once costs of continued use far outweigh any conceivable benefits (see examples in discussion below). Nor does it explain why some people find it so difficult to quit or why people often relapse after long periods of abstinence when the adverse withdrawal symptoms have disappeared.

In recent years neuroscientific studies have supplemented the above picture by suggesting that drug addiction involves complex, gradual, and enduring changes in the brain's reward circuits and control centers. These occur because certain drugs stimulate the release of excessive quantities of the neurotransmitter dopamine. These changes prioritize drug use and sensitize drug users to drug use cues, in effect giving rise to strong and persistent urges to seek out and use these drugs. They also reduce drug users' ability to exercise cognitive control over those urges. Both of these points are elaborated below (Robinson and Berridge 1993; Volkow et al. 2007).

On the first point, the implicated reward circuit – also referred to as the mesolimbic system or mesolimbic pathway – is comprised by the ventral tegmental area, nucleus accumbens, parts of the prefrontal cortex (namely, the orbitofrontal and anterior cingulate cortices), basolateral amygdala, and hippocampus. Animal research shows that this circuit plays a critical role in reinforcement learning by controlling behavior via the association of pleasant outcomes with certain environmental cues and behaviors. For instance, when a person engages in behaviors typically conducive to survival and reproduction – e.g., eating, sex, and positive social interaction – this prompts the release of dopamine into the mesolimbic system from the dopaminergic cells in the ventral tegmental area. This activates the reward circuit producing a pleasurable sensation and creating an association between that behavior and the prospect of reward. From that point onward, environmental cues associated with that behavior are tagged as salient – as carrying the prospect of eliciting pleasure – and thus as worthy of pursuit. However, while this mechanism plays a crucial role in promoting survival – it makes cues for behaviors that are conducive to survival particularly salient, which leads us to notice them and to do things that promote our survival – it is also prone to being "hijacked" by certain drugs (NIDA 2010).

When those drugs are taken, they stimulate the release of dopamine into the reward circuit (or mimic dopamine's action or prevent its reuptake from the synapse), often at levels many times greater than those elicited by normal survival-conducive behaviors. This has several deleterious effects. First, because

levels of dopamine released in response to taking these drugs are so much higher than levels of dopamine released in response to normal survival-conducive behaviors, drug-seeking and drug use and related environmental cues become associated with the promise of greater reward than other behaviors (Robinson and Berridge 1993; Kalivas and Volkow 2005; Volkow et al. 2007). Drug use becomes prioritized over other things, and this, in turn, can lead to repetitive drug use. Second, tolerance for the drug develops with sufficiently frequent use – i.e., greater quantities of the drug are needed to elicit the same degree of pleasure. This is due to a buildup of dopamine in the synapse which blocks subsequent dopamine action and also leads to a decrease ("downregulation") in the number of dopamine receptors at the synapse (Volkow et al. 2007). This effect further decreases the degree of reward elicited by normal survival-conducive behaviors (rather than just de-prioritizing their salience in relation to drug use) and produces a gradual escalation in the dose of drug required to produce the same pleasurable effect. That, in turn, further impairs dopamine's ability to perform its function in the reward circuit. After sufficiently frequent and prolonged use, the person no longer gains pleasure from using the drug but needs to use it merely to feel normal (NIDA 2010). Third, as addiction deepens, adaptations at the molecular level become ingrained in the parts of the brain's reward pathway as connections between neurons involved in coding for the salience of drugs are strengthened (Kasanetz et al. 2010). This results in increased frequency and strength of drug cravings triggered automatically even by casual exposure to cues like the sight of drug paraphernalia.

Research conducted by Nora Volkow and colleagues (Goldstein and Volkow 2002; Kalivas and Volkow 2005; Baler and Volkow 2006; Volkow et al. 2010) suggests that drug use also results in impaired cognitive control. The prefrontal cortex is implicated in cognitive control – it registers different impulses, detects conflicts between them, and selects the impulse that will lead to action. What appears to happen in addiction is that connections between parts of the brain that register reward and salience (the nucleus accumbens and ventral pallidum), memory and learning (the amygdala and hippocampus), and drive and motivation (the orbitofrontal cortex) become hyperactive, while at the same time connections with cognitive control and behavior inhibition (prefrontal cortex) are weakened. This results in a positive feedback loop of the reward-memory-drive aspects of decision-making that bypasses cognitive control. Volkow and colleagues conclude that addiction is thus a disorder of "disrupted self-control" (Goldstein and Volkow 2002; Kalivas and Volkow 2005; Baler and Volkow 2006; Volkow et al. 2010). In effect – according to their interpretation of the neuroscience – the fast impulsive system overtakes the reflective slower system: addiction-related behavior is seen as largely stimulus-driven and subject to minimal conscious control.

In conjunction with studies which suggest that drug addiction is 50 % heritable (Sellman 2010, p. 7; NIDA 2010), this picture of drug addiction has been taken by some as support for the claim that drug addiction is a disease of the brain – albeit an acquired one – and that drug-seeking and drug use are symptoms of a brain disease rather than genuinely intentional actions. Society's focus should therefore shift from holding drug-addicted people responsible for the crimes they commit as

a result of their drug addictions to developing, offering, and maybe even compelling them to undergo medical treatments to cure this disease. Supporters of this position (Leshner 1997; Kosten 1998; Gastfriend 2005; Kasanetz et al. 2010) either explicitly or tacitly endorse the view that once we acquire a greater understanding of the mechanisms and causes involved in drug addiction, all that will be left is to treat drug addiction rather than to punish drug-addicted offenders.

In response to these claims, Stephen Morse has argued that neither the *disease status* of drug addiction nor the *causal role* that implicated brain changes play in subsequent criminal misconduct can diminish addicts' responsibility for the crimes that they commit. Mere causation, on his account, cannot undermine responsibility because if we claimed that causation undermined responsibility, then nobody would be responsible for anything in a physical universe like ours where causation is everywhere (Morse 2006a, p. 405). He also argues that it is not clear why responsibility should be diminished only when behavior is caused by conditions categorized as pathologies (Morse 2011, p. 163), especially when it is far from clear which changes should be labeled as pathological (e.g., see Nadelhoffer and Sinnott-Armstrong 2013 for different accounts of pathology and disease; Vincent 2008 or Watson 2012 on the troubling relationship between pathology/disorder and criminal responsibility). Having rejected these claims about how drug addiction diminishes responsibility for criminal misconduct, Morse then considers how drug addiction fits with more legally conventional accounts of excuse.

Excusing Conditions and Addiction

Could addiction diminish responsibility for crimes committed to support that addiction in some other way though? Ordinary judgments of responsibility rest on a folk-psychological distinction between weakness of will and compulsion (Kennett 2001). The *weak-willed* agent acts in accordance with desires that run contrary to her better judgment; we think that had she exercised self-control, she would have succeeded in bringing her actions into line with her judgment. In contrast, in the case of *compulsion*, we think that the desire or urge on which the agent acts was, at that time, irresistible. Her attempts at self-control fail or would fail. The ordinary view holds that while weak agents are fully responsible for their actions, compelled agents are not fully responsible. But since weak agents and compelled agents may appear indistinguishable from the outside – they may judge and act alike – there may be difficulty in deciding whether the agent performing the act is weak and blameworthy or compelled and at least partly excused. This problem is particularly acute for the criminal law, which raises the question of how courts might determine whether a particular desire was irresistible or merely not resisted? Should courts even try to do this? And could neuroscientific evidence play any role in helping courts to decide?

Standardly it is *compulsion* and *irrationality* – i.e., two possible effects of addiction on people's agency-relevant mental capacities – as well as *coercion* (also called *duress*) that have potential to diminish criminal responsibility. Stephen Morse's view on the availability of these excuses to addicted persons is clear:

> Most addicts should be held responsible for most crimes other than simple purchase or possession, for purely personal use and for use itself. In general addiction does not sufficiently undermine either cognitive or control capacities to excuse the addict for other crimes, and virtually all addicts can be held responsible for not taking the steps to prevent them from engaging in addiction related crime. (2011, p. 173)

Compulsion on Morse's account involves being forced to do something against your will by either an *external* or an *internal* force. For instance, when person A grabs person B's hand and hits person C with it despite B's resistance, that's compulsion by an external factor. Another kind of compulsion occurs when the compelling force comes from inside the agent – for instance, from an irresistible urge which is so strong that it overpowers any efforts at self-control that the agent might make. The thought that some people might be compelled to use drugs is an instance of the second (internal) kind of compulsion.

Genuine compulsion, according to both those who endorse a *choice model* of addiction (e.g., Heyman 2009; Pickard 2011; Morse 2011) and those who endorse a *brain disease model* (Leshner 1997; Volkow et al. 2010), bypasses intention and robs behavior of its status as action. But choice theorists argue, against proponents of the disease model, that drug use cannot count as compelled because it is not like a tic or a reflex. It is not, Morse insists, analogous to hanging by one's fingernails over a cliff where there is a physical limit on one's powers of resistance. He argues that if addicted people's urges to obtain and use drugs were literally irresistible, then no addict should ever be able to resist using drugs in response to incentives. But yet, as choice theorists point out, drug use is responsive to local contingencies such as price or the presence of the police, which suggests that it is intentional. Drug users can certainly *delay* using if the stakes are sufficiently high, for instance as in Morse's example of a person facing court for public drunkenness who restricted himself to a single drink on the morning of his court appearance. Heyman (2009) further argues that everyone *stops* using drugs when the costs become too high, citing data that most people who have ever satisfied the diagnostic criteria for substance dependence eventually quit without treatment. In fact, the data he cites indicate that drug users are capable of exercising control over their use given even trivial incentives. He takes this to indicate that the choice to use drugs and any associated criminal conduct is not compelled. It is accordingly voluntary behavior for which the user is properly held responsible.

In contrast, the strength model of self-control described by Baumeister (2003) sees self-control as a depletable resource. Self-control, or strength of will, requires cognitive resources and these are limited (Levy 2011). On this model, a person who is addicted may initially resist the urge to use drugs, but eventually, if the urge persists, and without any other interventions, ego-depletion occurs, their capacities for resistance are exhausted, and they succumb much like the cliff-hanger. The strength model can thus explain the facts upon which the choice theorists rely while being consistent with the view that for some defendants persistent cravings over time overwhelm their powers of resistance. But even here choice theorists argue that giving in to urges to use drugs is not akin to losing one's grip. Morse argues that because giving in involves intentional action, "it is [thus] distinguishable from purely mechanical signs and symptoms" and so compulsion is absent (Morse 2011, p. 173).

At issue is precisely *how should compulsion be characterized*? If, by definition, nothing that counts as *action* can be compelled, then the defense of compulsion will only be available in situations of external force. After all, if one's internal states mechanistically produce behavior which is not action, (because not intentional) then the relevant defense would surely be one of automatism. One must however concede that the defense of automatism is unlikely to be available for crimes committed in the course of addiction. But if that is right, then is it not plausible that both *choice* and *disease* theorists might have the wrong account of compulsion? That they set the bar too high and mischaracterize the addict's predicament? Here is an alternative characterization of compulsion which does not yield the result that the behavior at issue ends up being viewed as non-intentional. In addiction, persistent and insistent drug-related thoughts and cravings dominate the agent's attention and eventually exhaust their self-control resources. At some point the agent loses their grip (metaphorically speaking) *on their prior resolution or intention to abstain* (see Holton 2009 and Levy 2006 on judgment shift in the face of temptation), and then they use drugs intentionally. Kennett (2001, 2013) proposes that the correct analysis of the ordinary notion of compulsive motivation is of motivation that is largely impervious both to the agent's *values* and to available techniques of self-control, and there is good reason to believe that this condition is often satisfied in addiction.

However, even if the mechanistic account of compulsion were correct and even if addicts were not like the cliff-hanger, it still would not follow that addicts are merely weak-willed. Addicts might still have an excuse for drug-related crime, if it could be shown that drug cravings are *coercive* in the sense that failure to act on them would exact a cost on them which it is unreasonable to expect them to bear. In law, Morse tells us, duress obtains "if the defendant is threatened with the use of deadly force or grievous bodily harm . . .unless the defendant commits an equally or more serious crime" (Morse 2006b, p. 71). The excuse of duress thus does not impugn the agent's rationality or capacities for self-control. Instead it pictures the agent as facing a particularly hard choice. The law uses a "moralized objective standard that uses the person of reasonable firmness as the criterion" of what it is reasonable or not reasonable to resist (Morse 2011, p. 185). Threats of death or grievous bodily harm are objective indicators of a hard-choice situation. It would be unfair of the law to expect someone to resist in such circumstances, even if resistance were possible. For instance, when a bank robber threatens "The money or your life," the teller is coerced into handing over the money. Given the awful situation that she was in – a choice of sacrificing her life or handing over a substantial amount of the bank's money – we excuse the teller for doing what would otherwise have been wrong.

A central feature of coercion is that it involves hard choices. If that is not part of the scenario, then we do not have coercion. A bank teller who yields to the threat "The money or I'll call you a rude name" would not have recourse to the defense of coercion. Morse argues that in the case of criminal activity to support drug use, the choices that addicted people face are more like the second bank teller's choices. He denies that the pain of withdrawal or the prospect of continued anhedonia is sufficient for addicts' actions to fall under the excuse of coercion or duress. In most cases, he says, withdrawal "is not terribly painful" and can be medically managed.

While addicts may (rationally) take drugs to avoid dysphoria, they do not fear it in the way that death is feared. This conclusion appears to follow from his prior argument that urges to use drugs are not compulsive; if the addict were threatened with instant death if he seeks or uses drugs, then assuming he wants to live "as much as the cliff-hanger does, no addict would yield to the desire" (Morse 2011, p. 180). The cliff-hanger, by contrast, will eventually fall no matter what. Morse presumably thinks the same would be true if an addicted user were threatened with grievous bodily harm. If the addict would (rationally) choose dysphoria over death or grievous bodily harm, then the threat of dysphoria does not constitute a hard choice in the required legal sense to establish duress. He further suggests that because dysphoria and craving are "more purely subjective than death or grievous bodily injury," they are more difficult to assess than fear of death or grievous bodily injury. Few addicts he thinks "would succeed with a hard-choice excuse."

There are however at least two problems with Morse's blanket dismissal of coercion as an excuse in addiction. First, it is not clear that fear of death or grievous bodily harm should be the standard required for duress in minor property crimes, where no person is threatened or harmed (say breaking into a parked car and taking the wallet lying in full view on the seat or stealing the coins from a pay phone), or for low level dealing to other drug users. The threat or continuation of severe dysphoria might be sufficiently coercive in such circumstances to provide at least some excuse for the offence, just as severe hunger might. Second, it is not true of all addicts that the threat of death or grievous bodily harm deters them from using or that compelling behavioral evidence of this cannot be obtained. To the contrary, there are numerous accounts of hard-core addicts who continue using while extremely ill, who know that death is a very probable outcome, and who do so without wishing to die. In an ongoing study being conducted by two of the authors, respondents showed a keen awareness of the very real risk of death from their continued drug use, as well as serious health consequences, amounting to grievous bodily harms that they suffered daily:

> Oh it's very harmful, it's almost killed me, I had cancer last year [. . .], I had alcoholic hepatitis, I was in the hospital almost five times and I had cellulitis four times . . . yeah it really hasn't done me any favors. (R10)
>
> I think now I have kidney or liver problems, [. . .] because certain drinks. . . the pain is just . . . in my lower back, the kidney area [. . .] I can't stand up, I have to lay down and it . . . yeah, like I literally can't get up, it passes after about 45 minutes I think, I think it's just while the kidneys process it or something and it passes, but it's really intense pain. . . (R4)
>
> All my family died from grog, all my brothers, sisters, my mum . . . I found [. . .] my mum dead on the floor from grog. (R13)
>
> [A]nother thing that's affected me is so many of my friends have died of drug overdose, like my first friend killed herself in 1997 and since then I've been to like 30 funerals, 40 maybe. (R53)
>
> [T]here's 12 of us started out together. And I think two are in institutions and the rest are dead, and I'm here. So I guess, yeah, I'm counting my blessings there. Any time that could have been me. (R39)
>
> You've always got that in the back of your mind you're going to have a seizure, or you may not wake up. (R25)

These examples demonstrate that at least some addicted individuals do not cease using even when faced with imminent death or grievous bodily harm. Some of them – those who are addicted to expensive illicit drugs – will commit crimes to support their use. Does this mean that they fear dysphoria more than death? This is not obvious. On Morse's account of coercion, coerced choices are difficult but not baffling in the way that our respondents' choices to continue drug use in the face of death surely are. Is their situation best described as one of coercion, compulsion, extreme irrationality, or simply as a personal choice for which they are responsible in the ordinary way?

Morse argues that if addiction excuses criminal conduct, it must hinge on the addict's *irrationality*. But in what sense are these users irrational? They do not have any unwarranted false beliefs about the likely consequences of their activities. The view advanced here is that the desires of the addicted person are irrational in that they are not responsive in the ordinary way either to the person's own *beliefs* about the likely outcomes of their use or to their *values*. Deliberation for such persons cannot get a grip on choice. Indeed, many of the respondents in the above study expressed deep sadness at their failure to live the kind of life they would have valued living and the loss of a home, family, and career opportunities to their drug use. Here it is plausible that the neuroscience of addiction *can* shed light on this puzzling phenomenon. According to Berridge:

> Human drug addiction may be a special illustration of intense "wanting" that results from permanent sensitization of mesocorticolimbic systems. Sensitized "wanting" may rise to quite irrational levels. That is, the intensity of cue-triggered "wanting" to take drugs for brain-sensitized addicts could outstrip their "liking" even for pleasant drugs, outstrip their expectation of how much they will like the drugs, and outlast any feelings of withdrawal if they stop. Brain-sensitized addicts may be unable to give a reason for their drug taking in such a case. Indeed, there is no reason, there is only a cause for why they "want" so much. (Berridge 2009, pp. 384–385, internal citations removed)

In line with this, respondents in the above study of users would generate reasons for use in which escape from dysphoria was sometimes mentioned as was pleasure. But for many these reasons for use fell by the wayside in the course of their addiction:

> I used it as a coping mechanism sort of thing. Yeah but now it's just . . . it's not even fun anymore really, it just sort of becomes a . . . I don't know, more or less like a chore I suppose but yeah I just . . . I want to get away from it. (R29)
>
> It's . . . there was reason, early part, until I came to understand why I was behaving the way I was behaving. So in . . . no, not now. No. There's no reason. (R39)
>
> When I was 20, 30 when I was 40 my drinking was good, I had good times on the drink,. . . I'm just drinking for nothing [. . .] I'm just drinking for drinking sake now. (R24)

For these respondents the desire or urge to use drugs is largely detached from their assessment of the consequences of such use, or their desire for the effects that the drugs once used to produce, and from their overarching values. Their subjective experiences accord with Berridge's claim that in addiction wanting and liking become dissociated and with the neurological evidence he produces. Now, as Morse duly acknowledges, neurobiological and psychological states that are signs

of addiction are states that “are mechanistically produced.” The question is how these states might affect responsibility. Insofar as the addicted person acts “for nothing,” for “no reason” that they can fathom, it appears that their defense may be *irrationality* rather than *coercion*. Insofar as they act unwillingly, doing something they neither like nor value, it appears that they might satisfy the ordinary, if not the legal, understanding of *duress* or *compulsion*. They do not act of their own free will.

On any of these interpretations, it would be unjust to hold such individuals, in whom wanting and liking have become dissociated, fully responsible for criminal actions arising from their addiction unless the following arguments succeed. Addicts must be (1) responsible for becoming addicts *and* this responsibility for actions in the past at a time when many of them were adolescents or children is sufficient to support full criminal responsibility as adults, or (2) the coercion, compulsion, or irrationality to which they are subject does not prevent the exercise of diachronic self-control and the availability of diachronic self-control is sufficient to support a finding of criminal responsibility. The next section contends that there are hard cases in which neither of these conditions are met.

Responsibility for Becoming Addicted

Morse argues that addicted people have only themselves to blame for their addiction. In his view, apart from infants born to mothers who used drugs during pregnancy, nobody is compelled or coerced into drug use. Rather, initial experimentation with drugs is usually a voluntary choice. People normally start experimenting with drugs in mid- to late adolescence, by which stage they are sufficiently psychologically mature to be held responsible in a court of law. And the risks associated with drug use are well publicized so there is little excuse for not being aware and taking heed of them. Bad social circumstances are likewise not a ground for excuse since few people from underprivileged backgrounds turn to crime. And to the extent that addicted people are to blame for their own predicament, they are not entitled to cite their predicament as an excuse.

While it is possible that a proportion of addicted people bear at least some responsibility for their addiction, a number of considerations are presented below to explain why such responsibility may in fact be absent or diluted to such a degree that it is highly dubious that this could be sufficient to ground a finding of criminal responsibility at a much later date and to extinguish excuses such as compulsion or coercion which might then be present.

First, a substantial portion of addicted people are first exposed to drugs at an extremely early age. One of the users that was interviewed in the above study received his first line of speed from his older brother’s friend at the age of ten. Others grew up with alcoholic parents who treated them as “drinking buddies” from a very young age. Another subject reports:

> I can't remember before I used. It's my whole life. Drugs have been my whole life. I remember at five sitting there drinking wine and eating mull cookies, so that's all I really remember is drug use. (R38)

Second, from a developmental perspective, adolescence is an especially vulnerable period. Smith, Xiao, and Bechara (2012) as well as Crone, Vedel, and van der Molen (2003) report that although most mental capacities gradually and steadily improve from childhood into adulthood, not all mental capacities follow this linear developmental trajectory. For instance, it turns out that younger and more developmentally immature children perform better on the Iowa Gambling Task than older and developmentally more mature early adolescents, not until later adolescence does performance recover. Smith and colleagues explain that:

> [t]his trajectory is thought to coincide with asymmetric neural development in early adolescents, with relatively overactive striatal regions creating impulsive reward-driven responses [in adolescence] that may go unchecked by the slower developing inhibitive frontal cortex. (2012, p. 1180)

This suggests that at some points during the process of maturation, mental capacity differences between adults and adolescents can be significant and that the reflection and foresight expected of adults is not an appropriate standard to apply to adolescents.

Third, the implicit focus on illegal drugs that permeates this discussion is regrettable. It makes it seem as if people must always surely be blameworthy for their initial decision to use potentially addictive substances. But this ignores the fact that most people in Western societies use addictive drugs recreationally at some stage in their lives, and most people do not become addicted. Addiction occurs at a fairly stable rate among exposed individuals, and those who become addicted may have taken no more risks than those who do not, but rather they were simply the unlucky ones who have a genetic or other predisposition towards becoming addicted (Sellman 2010, p. 7; NIDA 2010). Because the illegality of drugs is imperfectly correlated with their addictiveness (O'Brien and McLellan 1996), those who use and subsequently become addicted to illegal drugs might at best be blameworthy for breaking the law but not for taking unreasonable risks of addiction. In any case, as examples quoted from the above study illustrate, illegal drug users are more likely to be exposed to drug use at a very early age when they could not be blamed either for breaking the law or for taking unreasonable risks. Further, the focus on illegal drugs overlooks the promotional activities of companies who manufacture and market tobacco and alcohol, as well as governments who sanction this use and collect taxation revenue from sales of these substances. These groups are arguably also at least partly responsible for many people's addictions.

Finally, there is disquiet in philosophy about whether this "historical tracing" (Fischer and Ravizza 1998) approach can justify the practice of discounting the exculpatory value of mental incapacities for which we are responsible. One problem is that we must often go back so far in time to find the initial faulty action – the one which allegedly started a person off on the path of eventually committing a criminal offence as a result of being addicted. It stretches credulity to suggest that

the reason why this person is *now* blameworthy, despite their currently impaired mental capacities, is because their much younger self should have foreseen this eventual outcome all those years ago. Put simply, nobody (particularly children and adolescents) has nor can be expected to have that much foresight.

Of course it might be argued that the person whose drug use becomes problematic will experience negative outcomes well in advance of contact with the legal system. They will have had both ample warning and ample opportunity to change their ways. The problem with using this point to dismiss or to depreciate the exculpatory value of addiction is that gradual changes – such as increasing tolerance – may pass unnoticed, and by the time the negative consequences are forced upon the person's attention, their addiction is already established. Given that addiction may be established at a relatively young age, the point about foresight still holds.

The other problem with the tracing approach is that the *content* for which we wish to blame people, i.e., the criminal offence with which they are charged (e.g., possession or use of drugs, burglary, mugging, or perhaps even killing someone), ends up being very different to the content of the allegedly faulty action to which we trace things back (e.g., that they experimented with a potentially addictive substance) (Benchimol 2011).

These four considerations entail that responsibility for becoming addicted should not be a default assumption in criminal proceedings. Moreover, even when the defendant does bear some responsibility for becoming addicted, this will usually be an insufficient basis upon which to assign responsibility for their later criminal conduct.

Diachronic Self-Control and Responsibility in Addiction

Diachronic self-control is a form of control exercised in advance of an experienced temptation. It has two broad forms (Kennett 2001). First, the agent may manipulate her future circumstances to minimize the chance of the temptation arising or to ensure that the temptation is not acted upon. Take the case of smoking. Someone who is trying to quit smoking may decide not to go to Friday night drinks at the pub or to put herself in other situations known to trigger cravings. Or she might raise the cost of satisfying the desire for a cigarette by making a public bet or commitment to remain abstinent. Or she might leave her wallet at home so that she can't buy cigarettes on the way home from work when the craving usually arises. Second, if these strategies don't work, she may try to act directly on the desire to smoke by, say, taking a medication that reduces cravings, or by engaging in psychotherapy.

The advantage of diachronic strategies of self-control is that they don't require as much willpower as synchronic forms of control since they can be put into place when we are not under the distorting or overpowering influences of temptation. The addicted person can at those times recognize the reasons they have for quitting and take steps towards this end. The thought is that the predictable craving for drugs in

the evening does not prevent one from seeing a counselor or a doctor in the morning when those cravings are absent or muted. Running with this line of thought, Stephen Morse argues:

> Even if addicts are sufficiently *irrational* or are so "internally *coerced*" as to warrant mitigation or excuse at the time they commit their substance related crimes, they should still be held responsible [. . .] because *they have lucid, rational intervals between episodes of use during which they could* act on the good reasons to *seek help quitting or* otherwise to *take steps to avoid engaging in harmful drug-related behaviour*. (191, emphasis added)

Morse's argument is persuasive. The availability of techniques of diachronic self-control casts the net of responsibility wide and makes it more difficult to establish an excuse to criminal conduct on grounds of internal coercion or diminished rationality. It is probable that many people charged with drug-related crime have not faced a sufficiently hard choice to count as being internally compelled, or they have had adequate opportunity to exercise diachronic self-control with respect to their offending behavior. Nevertheless, Morse overlooks a category of users – a clinical subgroup – to whom this argument does not apply, and it is argued below that holding *this* category of addicts fully responsible for their criminal misconduct may well be unjust.

Limitations of Diachronic Self-Control in Addiction

There are two kinds of barriers to successful diachronic control in hard cases of addiction – that is, those cases that fit the diagnostic criteria of being chronic and relapsing, which persist beyond the late 1920s, and that involve clear and significant negative health and personal consequences. *Internal* barriers include (1) myopia for the future, an incapacity to foresee or pay attention to future consequences; (2) an inability to project oneself into, and so to plan realistically for, a future in which one is abstinent; (3) poor physical health; and (4) monopolization of attention which restricts one's thinking to an almost wholly synchronic focus. *External* barriers include (1) a lack or nonavailability of treatment options, (2) ineffective treatments, and (3) environmental factors that a person can't control, such as proliferation of liquor outlets and intrusive advertising, or a culture of drug use that they can't easily remove themselves from for legitimate reasons like poverty. Two of these factors which have particularly pronounced effects on this clinical subgroup's ability to exercise diachronic self-control are elaborated upon below.

An important aspect of diachronic self-control is mental time travel, i.e., the ability to project oneself into a personal future. Mental time travel allows us to plan for the future, secure our projects, and unify ourselves across time. It underwrites exercises of diachronic self-control. If hard-core addicts are highly fragmented or synchronic selves as some of the data suggests (e.g., Ainslie 2011), then they will not be able to project themselves into a personal future or identify with their future self in ways which motivate successful self-control. The temporary absence of craving is not sufficient to secure the availability of strategies of diachronic self-control in addiction.

Neurological and behavioral evidence suggests that diachronic capacities can be impaired in addiction. The work of Ainslie and colleagues shows that addicts apply a steeper discount rate to future consequences than others, suggesting that these consequences are less vivid to them. Other work done by Bechara, Dolan, and Hindes (2002) and Bechara (2005) on the Iowa Gambling Task also suggests that there is a subcategory of users who are insensitive to future consequences. This task registers on the one hand a choice for low- or high-risk decks, and on the other hand via skin conductance response registers emotional arousal and stress. Normal participants initially choose cards at random and over time develop a preference for the low-risk decks that give lower rewards but pay more in the long run. Before they can consciously describe why they have chosen the low-risk decks, they develop an anticipatory skin conductance response before choosing from the high-risk deck, indicating a feeling of stress. Persons with damage to the prefrontal cortex do not develop an anticipatory skin conductance response and keep choosing cards from the high-risk deck. Bechara distinguished three subgroups when he presented the test to substance-dependent people. The first group reacted like the normal participants; they developed the skin conductance response and started choosing the low-risk decks. This group was also higher functioning than the other two groups. The second subgroup reacted in the same way as the participants with prefrontal cortex damage: they didn't show anticipatory skin conductance responses and kept choosing from the high-risk decks. Bechara suggests that this group is "myopic for the future." The third subgroup kept choosing the high-risk decks, but they showed high skin conductance anticipatory responses (excitement) every time they chose a card from the high-risk decks. Bechara suggests that this group is highly sensitive to reward with poor impulse control.

Bechara's work has the following significance. Drug users in the first group who are responsive to incentives in the usual way would probably not satisfy the conditions for an excuse of coercion or compulsion or irrationality. One might suspect this group encompasses the majority of users who, as Heyman points out, cease using drugs without assistance as they mature and acquire life responsibilities. The third group lacks *synchronic* self-control. They may be able to institute some measures of diachronic self-control, but given their hypersensitivity to reward their self-control will be very vulnerable to external undermining by drug cues and the like. The second group shows a reduced capacity to imagine future consequences and to learn from negative consequences. This group cannot readily avail themselves of the techniques of diachronic self-control. Depending on the severity of their impairment, their responsibility for offending behavior may also be reduced.

The above use of the Iowa test or related neuroimaging in the legal context to determine which subgroup an addicted offender belongs to, or to assess their capacities for self-control, is only speculative at this stage. As Glicksohn et al. (2007, p. 202) point out, a sizeable minority of normal subjects also show impaired performance on the Gambling Task. However, if more specific and sensitive tests became available, they could, in principle, be used to help discriminate between those people who *cannot* control their drug use without considerable external

supports and targeted treatment, and those people who simply *do not*. The above should certainly not be taken to suggest that such technologies could by themselves determine whether responsibility was diminished or not. But it is possible that neuroscientific evidence could supplement behavioral and clinical evidence and, importantly, could be used at the sentencing stage to suggest the response to the offender that would most likely be effective in addressing offending behavior – whether pharmacological treatment, behavior modification therapies, or punishment.

Another important way in which addicts can exercise diachronic self-control is via seeking treatment for their addiction. Even if addiction is a disease, Bonnie (2002) points out that having a disease is not of itself an excusing condition. With this status comes responsibility – responsibility for seeking and complying with treatment. It is true that in addiction the rates of seeking treatment voluntarily and complying with it tend to be low (Chandler et al. 2009, p. 189). However, although treatment-seeking is *delayed* in addiction, most long-term addicts do seek treatment numerous times. Emmelkamp and Vedel (2006) estimate that on average it takes people 8 years and many tries for individuals to successfully overcome their addiction. The problem, though, is that at present there are actually no gold standard treatments available for addiction. Seeking treatment is often further complicated by waiting lists, costs, and exclusion criteria (e.g., for the use of methadone or psychiatric comorbidity). The lack of availability of effective treatment and support for those with serious addictions, particularly for the poor and disadvantaged, constitutes a serious external barrier to the successful exercise of diachronic self-control for which the addicted person cannot be held responsible. After all, there can only be a responsibility to do what is in one's power – i.e., to exercise the strategies of diachronic self-control that *are* available and effective – but if none are available or effective, then this is hardly something for which an addicted offender can be blamed.

Conclusions and Future Directions: Responsibility Without Blame

It is likely that many, perhaps most, people who satisfy the criteria for dependence on either licit or illicit drugs will lack a legal excuse for criminal offences committed pursuant to their drug use. Their drug use is responsive to a sufficient range of incentives, and while they may find it difficult to refrain from using drugs and this may involve some discomfort, this will not likely rise to a level that would provide them with a complete or partial excuse for drug-related criminal offences. For such people the criminal law and threat of punishment is capable of acting as a deterrent as well as a reminder of their responsibilities to develop and to exercise self-control.

However, attempts to refute or dismiss the neuroscientific evidence of responsibility-relevant impairments in hard-core users, or to draw conclusions about the responsibility of all addicted people by reference to the capacities of the majority of substance-dependent people, relies on a faulty generalization. It assumes that addiction is homogenous so that evidence that *most* addicted persons are responsive to incentives and can exercise control is taken as evidence that *all* can. It has been

argued that for a significant subgroup of substance-dependent people – those hard-core long-term addicts for whom numerous attempts to quit have failed – the issue of responsibility is not settled by reference to what most addicts can do. This is the group that the above discussion has focused upon and for whom the cited scientific evidence seems particularly relevant.

In regard to these people, it is hard to resist the conclusion that they are relevantly compelled, coerced, or irrational *and* that they have either not had adequate opportunity to instigate self-control strategies, including receiving treatment that would have prevented their offending, *or* that they have mental impairments that render those strategies largely unavailable or ineffective. It seems unjust to hold these individuals fully responsible for their misconduct and to blame them for it. Moreover, given that a central criterion for addiction is continued use in the face of significant negative consequences and given that some addicts continue using despite the daily threat of death and the actuality of pain and serious bodily harm, the threat or the actuality of legal punishment is unlikely to have any further disincentive effect. It only inflicts further misery and disadvantage upon this group.

However, the idea that addiction could provide a substantial or complete defense to serious criminal misconduct and that addicts whose criminal offences have harmed others should simply be released onto the streets is also unpalatable. This raises the question of what dispositions ought to be available to courts. Although the constraints of space do not permit a detailed elaboration of the following point, there is much that commends itself in Nicola Lacey and Hannah Pickard's (2012) recent "responsibility without blame" approach. On Lacey and Pickard's account, the only effective way to undo the impairments to agency that spring from drug addiction is via employing the fragments of agency that addicted people still retain. Lacey and Pickard suggest that by treating people as responsible agents and by making them accountable for their decisions, we can bootstrap their agency and responsibility into existence. However, blame is counterproductive to this therapeutic enterprise on their account since it further undermines the individual's sense of agency by reinforcing feelings of failure and inadequacy. And for this reason they suggest that an approach which has been successfully employed by clinicians – that of responsibility without blame – could also be usefully carried across into the legal context. This is, admittedly, a forward-looking approach to responsibility, in contrast to the backward-looking approach that is currently the basis for retributive criminal punishment practices. However, despite being forward-looking, it is not simply a consequentialist approach, because it does not give up on the core notions of agency and responsibility in favor of a system of incentives and disincentives. Rather, it has at its core the Kantian notion of respect for persons, which it aims to promote and to foster by treating people as responsible for their misconduct (without at the same time blaming them for it) in order to help them to develop the mental capacities that agents need to possess. Arguably this is what specialized drug courts attempt to do, and the broader implications of Lacey and Pickard's approach for the law deserve more detailed consideration.

Acknowledgments The authors are grateful to the Australian Research Council for their support of project DP 1094144 *Addiction, Moral Identity and Moral Agency: Integrating Theoretical and Empirical Approaches*. They especially thank the participants and staff of the Drug and Alcohol Services unit of St Vincent's Hospital (Sydney) – in particular, Rankin Court and Gorman House – as well as Wayne Hall and Adrian Carter for their helpful comments and practical editorial on this piece.

Abstract

This chapter provides an overview of policy and regulatory issues relating to the use of neuropharmaceuticals for cognitive enhancement in normal persons without a cognitive disorder. It draws on experience with a range of policy and regulatory approaches to alcohol, tobacco, pharmaceutical drugs, and illicit drugs and focuses on approaches that target rates of drug use in the population as a whole. The focus on regulatory interventions for the control of neuropharmaceuticals is important because a range of pharmaceutical drugs is often reportedly used and advocated for enhancement purposes. We also examine how more public health interventions such as awareness raising, education, and stigmatization could be used as preventive strategies to reduce the use, and harm associated with the use, of neuropharmaceuticals for cognitive enhancement.

Introduction

The recent increase in neuroscience research on human cognitive functioning has prompted speculation about the potential for developing new interventions, such as neuropharmaceuticals, that will enhance cognitive function in persons whose cognitive performance is normal, that is, unimpaired by disease or injury. This speculation has been encouraged by research reporting improved cognitive performance in "healthy controls" in response to drugs intended for use in the treatment of cognitively impaired patients, e.g., persons who have suffered strokes or head trauma.

This chapter provides an overview of unique policy and regulatory issues raised by the proposed use of pharmaceutical drugs for the purpose of cognitive enhancement in persons without cognitive impairment. Current discussions about the possibility of this type of cognitive enhancement focus on the use of neuropharmaceuticals to improve executive function, memory, attention span, concentration, and alertness. The literature cites some empirical evidence that students, particularly those at elite colleges in the USA, use prescription stimulants such as Ritalin (methylphenidate) or dexamphetamine/mixed amphetamine salts (Adderall) as study aids (DeSantis et al. 2008; Teter et al. 2006). Illicit drugs may also be used for cognitive enhancement purposes, but this chapter will focus on policy and regulatory interventions for the control of neuropharmaceuticals. This is because there is an increasing call for the prescription of neuropharmaceuticals for cognitive enhancement purposes. However, such a policy change could trigger a rapid growth in drug use that may lead to unanticipated harm including addiction. This chapter draws on experience with a range of policy and regulatory approaches to a variety of psychoactive substances that include alcohol, tobacco, pharmaceutical, and illicit drugs. An assessment of different approaches to controlling or regulating

these substances can provide useful insights in designing practical regulatory approaches to the emerging enhancement use of neuropharmaceutical drugs.

Neuropharmaceuticals putatively used for cognitive enhancement can be framed in different ways that reflect similarities between their patterns of use and the use of illicit drugs, prescription drugs, and "lifestyle" drugs. Different fields use different competing frames or discourses to capture the phenomenon. These range from the paradigm of drug misuse and prescription drug abuse (that is often encountered in the public health literature) to the paradigm of "cognitive enhancement" most often encountered in interdisciplinary bioethics discussions (Forlini and Racine 2012; Racine 2008). We also examine the possible roles of public health interventions such as awareness raising, education, and uses of stigma that could be used to prevent use and reduce harm arising from neuroenhancement use of these drugs.

Claims Made for the Enhancement Use of Neuropharmaceuticals

The safety and effectiveness of using neuropharmaceuticals as cognitive enhancers in healthy individuals remains uncertain, but this pattern of use has nonetheless been sympathetically discussed in leading scientific (*Nature*) and medical journals (*BMJ*, *Neurology*). This proposed use of prescription medications raises regulatory and public health policy challenges that need to be carefully considered.

The lack of scientific evidence on the safety and efficacy of neuropharmaceuticals when used for enhancement presents a major challenge to those seeking to make recommendations about policy and regulatory approaches. Nonetheless, professional bodies have attempted to develop policies in the UK (Academy of Medical Sciences 2008; British Medical Association 2007) and Canada (Government of Quebec 2009). The American Academy of Neurology, for example, has published guidance for neurologists on how to respond to patient requests for a prescription to improve their memory, cognitive focus, or attention span, on the assumption that such requests are already common in neurology practice (Larriviere et al. 2009).

Regulatory Options

A recent paper in the Lancet argued that the aim of drug policy should be to "promote the public good by improving individual and public health, neighbourhood safety, and community and family cohesion, and by reducing crime" (Strang et al. 2012, p. 71). Models of drug regulation vary according to the type of drug and the jurisdictions involved. This section examines the strengths and weaknesses of applying these different models of regulation to the use of neuropharmaceuticals for cognitive enhancement. Table 69.1 provides an overview of approaches and their major strengths and weaknesses.

Table 69.1 Summary of regulatory and public health approaches and their major strengths and weaknesses[a]

Approach	Description	Strengths	Weaknesses
Free market	No restrictions on the adult use of neuropharmaceuticals for cognitive enhancement	Promotes personal choice to engage in cognitive enhancement	Potential dangers if safety has not been established
			Resources wasted if efficacy is not established
			Incompatible with current regulation of putative enhancers
Market regulation	Psychoactive substances regulated through various measures including taxes and limits on sales and promotion	Avoid the potential negative consequences of prohibition while controlling use	Commercial interests selling these drugs have an interest in limiting the effectiveness of the system to maximize profits
Licensed users	People demonstrate an understanding of the risks and capacity to use the drugs responsibly before being allowed to use for enhancement	Promotes informed consent	Not currently feasible
			Challenging given varying levels of health literacy in society
Prescription system	Only licensed physicians can prescribe a drug which must be dispensed by a pharmacist	Supervision by health-care professionals	Possibility of diversion
		Ensures access for approved medical purposes	Availability through Internet pharmacies which are difficult to regulate
Prohibition	Unauthorized trade in psychoactive substances, whether illicit or medicinal, is a criminal offence	Clear regulation on nonmedical uses of medications	Creation and expansion of black markets
			Creates challenges because current putative enhancers are used as treatment for legitimate medical conditions
Public health education approaches	Reduce or delay initiation and prevent regular and dependent drug use	Cost-effective	Not very effective for prevention of use of illicit drugs, tobacco, and alcohol
Mass media and information campaigns	Use warning messages about the health impact of drug to influence attitudes and behaviors	Potential for widespread diffusion of information	Potential source of misinformation
Stigmatization and denormalization	Use of stigma to create a negative image for use of neuropharmaceuticals for cognitive enhancement	Not restricted to health agencies	Unintended consequences and collateral stigma of illness
		Can involve social control that is exerted by family and friends	Potential impact on users' self-esteem and societal acceptance of diversity

[a]See text for full details

Free Market Approaches

Some bioethicists have argued for a laissez-faire approach towards neuroenhancement. They have recommended a free market, suggesting that there should be no restrictions on the use of neuropharmaceuticals for cognitive enhancement (Sandberg and Savulescu 2011; Savulescu and Bostrom 2009). Greely and colleagues argued that easier access to cognitive enhancers should be allowed and no legal penalties be imposed on those who wanted to use neuropharmaceuticals without a prescription. Furthermore they suggest that the use of drugs should be viewed "in the same general category as education, good health habits, and information technology – ways that our uniquely innovative species tries to improve itself" (Greely et al. 2008, p. 702).

Bostrom and Sandberg have advocated a similarly liberal view in suggesting that treating nontherapeutic neuropharmaceutical use as misuse is inconsistent with the shifting border between therapy and enhancement. Bostrom and Sandberg (2009) argue that:

> To make the best use of new opportunities, society needs a culture of enhancement, with norms, support structures, and a lay understanding of enhancement that takes it into the mainstream cultural context. Consumers also need better information on risks and benefits of enhancers, which suggests a need for reliable consumer information and for more studies to determine safety and efficacy. (p. 333)

This liberal approach is inconsistent with international drug control treaties. The United Nations Drug Conventions are clear that unauthorized trade in psychoactive substances, whether illicit or medicinal, should be a criminal offence and consequently recreational drug use must be strictly controlled (Hughes and Winstock 2012). Furthermore, free market approaches are inconsistent with other regulatory approaches to the regulation of pharmaceutical drugs in developed countries, as we discuss below. The use of prescription neuropharmaceuticals without a prescription – including those used for cognitive enhancement – is illegal in most developed countries that are signatories to these international treaties.

Market Regulation

If the use of neuropharmaceuticals without a prescription was to become legal, the market could be regulated in different ways. For example, markets could be regulated in the same way as markets for other legal drugs such as tobacco or alcohol. The use of alcohol and tobacco is not prohibited and does not require a prescription, but their use is controlled by methods including the imposition of taxes, limiting availability, age limits on use, and restricting promotion of their use and when and where they may be used. These approaches have had reasonable success in limiting availability and controlling the use of some drugs. For example, raising taxes and limiting the availability of alcohol are moderately effective in

reducing levels of alcohol consumption and rates of alcohol-related problems (Babor et al. 2010; Room and Hall 2012). Regulatory controls on smoking in public places, workplaces, bars and restaurants have contributed to reductions in community smoking prevalence (Room and Hall 2012).

A major weakness with a legal regulatory system is that the companies who market the commodities have a major commercial interest in limiting the effectiveness of the system or in using the system to their advantage, e.g., by limiting competition to current market participants ("regulatory capture"). The continued effectiveness of regulatory systems depends on the vigilance and preparedness of governments to operate these systems in the public interest (Room and Hall 2012).

Licenses for Use

Some bioethicists have suggested a licensing system for the use of neuropharmaceuticals for cognitive enhancement. Bostrom and Sandberg have suggested that "enhancement licenses" be issued to people who demonstrate an understanding of the risks and a capacity to use these drugs responsibility. This would mean that users would be able to give informed consent and that any adverse effects of their use could be properly monitored (Bostrom and Sandberg 2009). Dubljevic proposes an "economic disincentives model" whereby users would be licensed, first paying fees for a course about effects and side effects, proving their knowledge by passing an exam, becoming registered as an enhancement user, and obtaining additional medical insurance (Dubljevic 2012).

This idea is not currently feasible under drug regulatory systems in developed countries. It seems reasonable to expect that such a licensing system would require a minimum demonstration of the safety and efficacy of putative enhancers to meet the requirements of informed consent and other criteria of moral acceptability (Racine 2010). It is not clear who should fund research to demonstrate this or whether consent could be free from coercive pressures to use a cognitive enhancer.

Prescription System

Prescription systems are designed to manage the medical use of drugs that have potentially adverse and beneficial health effects. Many illicit drugs were first used for medical reasons, and some illicit drugs (or drugs with similar effects) are still used as medicines, e.g., opioids and stimulants. Prescription monitoring systems can reduce irregular prescribing and patient utilization while allowing patients to access these drugs for appropriate medical purposes (Strang et al. 2012). Under prescription regimens, only licensed physicians can prescribe a drug which must be dispensed by a pharmacist, often in limited quantities to limit diversion. However, prescription regimens do not eliminate nonmedical use of neuropharmaceuticals because these drugs may be diverted to nonmedical use, e.g., by giving drugs to family or friends or selling the drug on the black market. This can make reduction of supply through traditional law enforcement difficult (Strang et al. 2012).

The prescription system can allow greater control by regulators. For example, in the USA the 2011 Prescription Drug Abuse Prevention Plan was introduced to reduce misuse and diversion of prescription drugs. The plan includes mandatory education for physicians who prescribe and pharmacies that dispense. Such programs are designed to prevent doctor shopping and drug diversion by allowing physicians and pharmacists to access patient records at the time of writing a prescription or dispensing a drug to ensure that the patient is not receiving multiple prescriptions from different doctors (Holmes 2012).

The emergence of Internet-based pharmacy services makes control of prescription drugs less effective and more challenging (Fischer et al. 2010; Strang et al. 2012). Websites may require a prescription but "rogue" websites may provide drugs without one (Nielsen and Barratt 2009). Online pharmacies are difficult to regulate closely because sites may only be available temporarily, they are difficult to trace, and their operation may cross international boundaries and jurisdictions (Orizio et al. 2011). Real-time monitoring may provide much-needed data about the prevalence of acquiring prescription drugs from online pharmacies and even reduce the overuse of prescription medications. Online monitoring of trends in drug use may also provide better information about broader patterns of "off-label" prescription drug use (Nielsen and Barratt 2009).

Regulation of online pharmacies is challenging, but it is even more difficult to regulate Internet sites where people may access information or supplies of pharmaceutical drugs. For example, social networking websites such as MySpace and Facebook have become a common marketplace for the buying and selling of prescription drugs (Stone and Merlo 2011). There are also websites advising users on how to simulate a disorder in order to persuade a doctor to provide a prescription.

It appears that prescription monitoring systems may reduce overall use, but their impact on reducing diversion or nonmedical use of pharmaceuticals is unclear (Fischer et al. 2010). Diversion is not likely to be effectively targeted by law enforcement approaches. It is likely to be more effective to put in place measures to reduce the overall use of the drug while ensuring that when it is used it has been prescribed appropriately (Fischer et al. 2010).

Strang and colleagues note two weaknesses with the regulation of drugs via a prescription system. Firstly, reduced rates of prescription of some drugs can produce an increased use of other prescription drugs with similar effects, as nonmedical users find alternative drugs to use when distribution of their preferred drug has been restricted. Secondly, restrictions on prescribing have the potential to deny medications to patients who require them for treatment (Strang et al. 2012).

Off-Label Use

Off-label use occurs when a prescription is provided by a physician for a reason other than the licensed purpose of the drug but generally for medical indications. The American Academy of Neurology guidelines adopt a laissez-faire approach that permits off-label use of enhancement, but this view does not capture the fact that off-label therapeutic uses of a drug are warranted under the proviso that physicians are using a drug to treat a patient (Larriviere et al. 2009). The Academy

of Neurology guidelines have been criticized for not providing helpful guidance to health professionals that is consistent with commitments to evidence-based medicine and socially responsible medical practice, and it is also at odds with the general understanding and justification of off-label prescription (Racine and Forlini 2010).

Explicit Enhancement Use of Neuropharmaceuticals

It has been argued that the use of neuropharmaceuticals for cognitive enhancement could be readily dealt with by incorporating explicit enhancement use into existing systems of pharmaceutical regulation (Greely et al. 2008). Bostrom and Sandberg argue that the present system for licensing drugs and medical treatments is overly constraining because it does not allow for the development and marketing of drugs that have a solely enhancing function (Bostrom and Sandberg 2009). They suggest that the "medicine-as-treatment-for-disease" framework creates problems for pharmaceutical companies and users who have to doctor-shop to find a physician who is willing to bend the rules by prescribing a drug for enhancement purposes. Some students admit simulating psychiatric symptoms in order to get prescriptions for drugs that they intend to use for enhancement purposes (Carroll et al. 2006).

Dubljevic proposes a system whereby a government agency would offer a licensing system for pharmaceutical companies to develop drugs that would be used for cognitive enhancement, on the condition that these drugs were first used to treat cognitive disorders (Dubljevic 2012). He suggests that pharmaceutical companies would be interested in this opportunity because of the large potential market for cognitive enhancers. However, given that pharmaceutical companies already have large markets for their products, it is not certain that they would be willing to take on the extra expense and medicolegal risk involved in marketing neuropharmaceuticals to healthy people for cognitive enhancement purposes. Previous attempts to market stimulants for cognitive enhancement have been abandoned (Bell et al. 2012). It is unlikely that pharmaceutical companies would be eager to fund studies to demonstrate the safety and efficacy of drugs to enhance cognitive performance in healthy people. The legal liability involved in providing drugs to healthy people would also be a deterrent because there may be less social tolerance for side effects and adverse events of drugs used electively for nontherapeutic reasons.

Prohibition of All Enhancement Use

In contrast to laissez-faire approaches, prohibition is a policy position which bans enhancement use of a drug. A parallel may be drawn between this approach and the anti-doping policy in competitive sports. In this model, athletes submit to a testing regime targeting a range of identified substances, and there are severe penalties for those who are identified as drug users.

An example of the application of this model to cognitive enhancement could be to drug test students for the use of drugs for cognitive enhancement. However, as in the case of illicit drugs, there is no compelling case for the effectiveness of

school-based drug testing in discouraging drug use by students (Roche et al. 2009). The neuropharmaceuticals used for cognitive enhancement purposes may be exactly the same substances used for the treatment of legitimate medical conditions, and it would therefore be very difficult to work such an anti-doping system in practice. Furthermore, a rigorous testing scheme is no guarantee against the use of performance-enhancing substances.

There are a number of other important reasons that make it hard to justify using drug testing to deter use of cognitive enhancers in educational settings. It may lead to the criminalization of such behavior. The resulting stigma and illegality of such use may deter patients from using these drugs for appropriate medical purposes. It may also unwittingly send the message that drug use is common and in fact normalize use. Furthermore, implementing a drug testing system would be costly and divert resources away from other activities such as education and treatment.

Public Health Approaches

Public health approaches to reducing drug-related harm include measures designed to deter individuals from using substances in ways likely to harm themselves or others. These approaches follow from a policy of prohibiting harmful use of a substance while recognizing that legal and regulatory prohibitions will not prevent all use. Measures to prohibit use or regulate markets, as described above, function to protect public health. However, more general prevention approaches also aim to stop people from starting drug use, delay initiation, or dissuade them from becoming regular and dependent drug users.

Examples of such measures include laws that prohibit driving while under the influence of alcohol or drugs, the public use of drugs, or being intoxicated in public places; public education about the risks of drug use; and the stigmatization of certain drug use or patterns of drug use (and thereby the people who use these drugs in these ways). Public health approaches can be implemented in a variety of settings, such as schools, the mass media, community settings such as the workplace, and in primary health care. Environmental interventions aim to limit the availability of dangerous substances, while educational interventions aim to raise community awareness and knowledge of the adverse effects of drug use.

Knowledge and awareness campaigns are generally ineffective in preventing the use of illicit drugs, tobacco, and alcohol (Babor et al. 2010). More effective strategies include psychosocial developmental interventions (e.g., resilience building programs in schools) and information campaigns to correct community misperceptions (e.g., about the prevalence of use of some types of drugs) (Strang et al. 2012). The latter is particularly relevant in the case of neuropharmaceutical use for cognitive enhancement because US college students perceive the prevalence of this type of drug use as much higher than the actual prevalence (Forlini and Racine 2009; McCabe 2008).

Targeted preventive interventions to curtail stimulant abuse among college students have been recommended. These include efforts to educate students about the dangers of illicit stimulant use, using a denormalizing approach, combined with health education to debunk myths and expose the risks involved while encouraging more appropriate study habits (Rosenfield et al. 2011). One limitation of this approach is that it places the onus on university administrations and neglects the role of physicians in prescribing these drugs (Forlini et al. 2013) and the societal pressures that encourage their use.

The mass media are important vehicles of public information (or misinformation) about the prevalence and risks of drug use. Mass media deserve special attention because of their overestimation of the extent of neuropharmaceutical use for cognitive enhancement (Forlini and Racine 2009; Partridge et al. 2011). Media guidelines may raise awareness of this problem. For example, the Australian Press Council has put forward recommendations on how the mass media should avoid certain messages when reporting on drug use (Australian Press Council 2001). Reports should avoid glamorizing drug use or unintentionally providing information on how to obtain a drug or how to use it in risky ways. Unfortunately these guidelines are not always followed when reporting on enhancement use of neuropharmaceuticals (Partridge et al. 2011).

Stigmatization and denormalization of the use of neuropharmaceuticals for cognitive enhancement deserve more attention given their fundamental role in policy and public health approaches to drug use. Current anti-tobacco campaigns which represent an example of the effects of stigmatizing smokers could tempt policy makers to use a similar approach to enhancement use of neuropharmaceuticals. Room and Hall (2012) argue that the main lesson from global experience with prohibitions of psychoactive substances is that such prohibitions are most successful when there is a strong community norm of abstinence. This approach contrasts with the free market arguments for the normalization (or at least the destigmatization) of cognitive enhancement use of neuropharmaceuticals (Bostrom and Sandberg 2009; Greely et al. 2008).

Denormalization and stigmatization are likely to be difficult approaches to implement in the context of cognitive enhancement in the face of markedly different stakeholder attitudes towards cognitive enhancement. For example, health-care providers condemn the nonmedical use of stimulants for academic performance enhancement, while college students may be more tolerant of such use among their peers (Forlini and Racine 2009). It will be difficult to change the very different mindsets of these groups with stigmatization campaigns.

Challenges in Assessing Regulatory Options

Lack of Evidence on Prevalence, Efficacy, and Harms

The lack of good quality evidence about the cognitive enhancement use of neuropharmaceuticals is a major challenge in assessing regulatory options. Early in the bioethics discourse about cognitive enhancement, there were recommendations

made for policy approaches on the basis of assumptions that the substances under discussion were being used widely across the population and they actually enhanced cognitive performance and were safe to use. However, there is an increasing awareness that such assumptions lack an evidence base and, in fact, may be false (Lucke et al. 2011).

Critics have questioned evidence from US studies of student drug misuse that have been used to justify claims that the use of neuropharmaceuticals for cognitive enhancement is widespread. The interpretation and relevance of these findings for cognitive enhancement has been questioned (Lucke et al. 2011). Other results emerging (Franke et al. 2011) show that the prevalence may be much lower than claimed. Media reports perpetuate the impression that prevalence of use is already high and increasing (Partridge et al. 2011). Data are needed from large-scale focused studies of cognitive enhancement to provide data that will inform appropriate policy development.

Recent reviews of the effects of putative neuroenhancing drugs, such as the stimulants, antidepressants, and acetylcholinesterase inhibitors, have not found convincing support for their efficacy (Lynch et al. 2011; Repantis et al. 2008, 2010a, b). In normal healthy people without any impairment, such as sleep deprivation, stimulants have a very modest impact on memory, and gains are more likely among those with lower baseline ability (Smith and Farah 2011).

Neuropharmaceuticals are regulated because of their potential to adversely affect health. Regular users may develop acute tolerance to the subjective effects of stimulants and often respond by increasing their dose, thereby increasing the risks of toxic side effects and of abuse and dependence. In the USA almost 1 in 20 nonmedical users of prescription stimulant medications meets criteria for stimulant dependence or abuse. Medical complications of acute stimulant intoxication include an altered mental state (from euphoria to psychosis), seizures, and cardiac arrhythmia (Kroutil et al. 2006). Debates about the cognitive enhancement use of neuropharmaceuticals have been criticized for ignoring the potential for abuse and addiction (Bell et al. 2012; Swanson et al. 2011). Concerns about minimizing the potential health effects of neuropharmaceuticals should be paramount in discussions about appropriate policy and regulatory frameworks.

Lack of Evidence of Effectiveness of Methods of Regulation

Drug policy is often contentious, operating in "a complex political terrain characterised by intense controversy, mixed opinion and unrelenting media attention" (Fraser and Moore 2011, p. 505). Ideally, evidence about the effectiveness of policy approaches should be underpinned by good scientific evidence about the effects of the substance in question. But as Strang and colleagues note, policy is often formulated to deal with problems of perceived immediate public importance (such as the emergence of a new type of psychoactive drug or a highly publicized drug-related death of a celebrity), rather than on the basis of scientific knowledge about the prevalence of

the drug's use or its likely harms (Strang et al. 2012). Public debate in drug policy is also driven more by values and politics than by scientific evidence. This context means that even with good evidence, emerging knowledge about neuropharmaceuticals may only be tenuously related to public perception, patterns of use, and approaches to policy and regulation. Evidence about the effectiveness of different policy approaches and their cost-effectiveness can nonetheless help both the public and policy makers to select policies that achieve the goals they desire (Strang et al. 2012).

The rationale for public health approaches may be debatable at this point in time. Outram and Racine have noted that there is a lack of empirical data justifying public health interventions. There is a risk that governments may act on the grounds of probable health risk instead of epidemiological data (Outram and Racine 2011a). Outram and Racine have noted the lack of critical reflection on the underlying rationale for reports that cognitive enhancement practices are rampant. They suggest that these reports constitute important actions from a social standpoint:

> . . . as it currently stands, cognitive enhancement is constituted in a way that challenges the creation of coherent and effective policy recommendations. The different approaches taken to the subject of cognitive enhancement appear to reflect this lack of cohesion. However, policy makers should not simply wait and hope that on balance the benefits turn out to be greater than the risks or to wait for definitional consensus. Some components of cognitive enhancement could be reduced down to clearly identified targets to be further examined. Then, if appropriate, policy should be created that is normative and, amongst other criteria, beneficial to the majority of the population. (Outram and Racine 2011b, p. 323)

Future Directions

So what is the most probable policy approach to the use of neuropharmaceuticals for cognitive enhancement? In the absence of a good evidence base on the safety and efficacy of such drug use, prohibition is likely to be the default position. This position is a precautionary one that aims to reduce the risk of adverse health outcomes.

The neuropharmaceuticals that appear to be used for cognitive enhancement are medicines that are already controlled through prescription systems. Patterns of use described in the bioethics literature as cognitive enhancement are achieved through the diversion of neuropharmaceuticals from their medical use, which is defined as a criminal offence in most countries. Examples include the fraudulent presentation of symptoms to a physician for the purpose of obtaining a diagnosis in order to obtain a prescription for a stimulant, or obtaining neuropharmaceuticals without a prescription, either from a friend or through the Internet. A physician who prescribes a neuropharmaceutical off-label for enhancement purposes to someone without a disorder is also acting illegally.

There is no simple answer to the best way forward in formulating policy approaches to the use of neuropharmaceuticals for cognitive neuroenhancement. Every approach has advantages and disadvantages, but international deliberations about policy must start from the basis of existing systems (Racine and Forlini 2009).

The feasibility and effectiveness of approaches may differ across jurisdictions and vary with the characteristics of the specific neuropharmaceutical under consideration and those who use it. Policy approaches to regulating covert drug use are challenging. It is especially difficult to regulate the use of neuropharmaceuticals which may have been obtained through diverse channels – including a prescription for off-label use that may be given in good faith by a physician or illegally accessed via the Internet without a prescription or manufacture and supply via the black market.

It is important to explore all logically possible options. Potentially useful strategies include targeted public health interventions, professional self-regulation to support existing guidelines for prescription, and developing more effective guidelines for medical professionals. Further examination may be warranted of the potential role that denormalization (or stigma) may play in discouraging enhancement use of neuropharmaceuticals. The framing of any such public discourse will be important if we are to avoid making it more difficult for people to access treatment and obtain help for psychological or health concerns arising from such drug use.

Public debates about the possible benefits and harms of using pharmaceuticals for neuroenhancement provide the best chance of developing sensible policies towards such use (Hall 2004). Meaningful deliberation about the ethical acceptability or regulation of neuroenhancement should not be based on speculation and poor-quality estimates of the prevalence, efficacy, and safety of the use of neuropharmaceuticals for cognitive enhancement. Ideally policies should be evidence based and informed by monitoring and evaluation of their impacts. However, in the absence of such evidence, many important ethical challenges can be addressed within the regulation of the use of neuropharmaceuticals for cognitive enhancement through the existing regulatory systems that govern illicit and pharmaceutical drugs.

Abstract

This section on Human Brain Research and Ethics is comprised of four chapters: ► Chaps. 71, "Clinical Translation in Central Nervous System Diseases: Ethical and Social Challenges"; ► 72, "Ethics of Sham Surgery in Clinical Trials for Neurologic Disease"; ► 73, "Research in Neuroenhancement"; and ► 74, "Brain Research on Morality and Cognition". The chapters cover a range of important ethical issues encountered in human brain research. This includes discussions regarding how current understandings of research ethics can be applied to translational clinical research in brain research, the ethical challenges faced when considering research related to neuroenhancement, and the relationship of human brain research to our basic understandings of morality and cognition.

Introduction

Human brain research inevitably involves ethical issues. While in large part these ethical issues are similar to those encountered in research in the life sciences in general, certain issues have been especially poignant in regard to this research. Chapters in this section address a set of these issues across a wide spectrum of human brain research. These include the ethical issues related to

translational neuroscience research, sham surgery in brain research, research in neuroenhancement research, and brain research on morality and cognition.

Translational neuroscience research is directed at ameliorating a spectrum of often devastating brain diseases, which may be associated with a change in cognitive capacity as well as troubling physical manifestations. In many cases, current treatment approaches are inadequate and clinical management is based on symptomatic management. These background conditions are complicated by the fact that many promising therapeutic approaches fail to demonstrate benefit when rigorously evaluated, underscoring the need for careful research before and after instituting therapeutic approaches. In their ▶ Chap. 71, "Clinical Translation in Central Nervous System Diseases: Ethical and Social Challenges" Jonathan Kimmelman and Spencer Phillips Hey review some of the basic ethical foundations for translational research (human subjects; integrity; and animal welfare) and then describe some of the ethical issues encountered over the continuum of this research. The continuum of translational research involves several stages: preclinical; early phase and hypothesis exploration; late phase; and post-licensure. Potentially problematic aspects of preclinical research include its design and oversight, bias, external validity, lack of aggregated information across preclinical research, and incomplete reporting. Given the importance of these issues to subsequent phases of translational research, Kimmelman and Hey highlight the importance of addressing their practical and ethical aspects. Early phase trials also raise concerns related to their non-therapeutic intent since many potential participants may have exhausted other therapeutic options. Therefore, potential participants' decision-making may be clouded not only by an underlying condition, but also by desperation, accentuating the need to ensure that consent to participate is actually informed and voluntary. In late phase translational research, the scientific and ethical aspects of selecting a comparator arm (such as a placebo or sham) warrant careful consideration. Finally, post-licensure testing can raise concerns about quality as well as appropriate oversight.

Due to concerns about the validity of brain research in humans that may be profoundly influenced by a placebo effect, sham procedures have been employed in some translational brain research, most notably in the evaluation of promising therapies for Parkinson disease. While using sham procedures may help mitigate some scientific concerns, their use also raises ethical concerns. After reviewing the nature of the placebo effect in assessing outcomes in neurologic disease, ▶ Chap. 72, "Ethics of Sham Surgery in Clinical Trials for Neurologic Disease" Sam Horng and Franklin G. Miller describe the ethical issues and practical implications associated with conducting sham surgery. An important ethical consideration in assessing a particular sham procedure relates to the risk of the procedure itself. Whereas some sham procedures do not pose any substantial risk (other than those potentially related to withholding an intervention that may be helpful), others involve certain harms and risk, such as those that require invasive neurosurgical procedures. Another important ethical dimension of sham surgery is the inherent use of deception in the context of clinical research, highlighting the need for transparency and consent regarding the nature of shams. Nevertheless, as in other translational brain research, obtaining consent may be especially complicated due to the manifestations of an

underlying disease. Horng and Miller conclude their chapter by reviewing an approach to assessing the ethical acceptability of research involving sham, drawing attention to areas that necessitate close attention.

While much human brain research is directed primarily at understanding and ameliorating human disease, another interesting body of research is aimed at neuroenhancement. That is, efforts related to improving the ability to perform mental tasks, activities, and functions, such as memory and cognition. ▶ Chap. 73, "Research in Neuroenhancement" Michael L. Kelly and Paul J. Ford describe and analyze the ethical concerns associated with this type of research. Neuroenhancement research can face familiar ethical issues regarding the assessment of risks and benefits as in biomedical research, but it also raises broad ethical concerns related to the possibility of successful interventions exacerbating social inequities and the long-term social implications that might arise from their use. Further, unlike much clinical translational brain research, neuroenhancement research tends to involve participants who are not ill, thereby shaping the ethical analysis somewhat differently. As such, Kelly and Ford suggest that given the limitations of a biomedical research ethics model in analyzing neuroenhancement research, a "consumer-based model" of ethics should be employed. Although a consumer-based model upholds the need to attend to core ethical concepts such as risks and benefits, it gives wide berth to the goals and values of healthy individuals regarding neuroenhancement research that are not constrained by particular notions of disease. While this nascent model is responsive to a range of ethical concerns in neuroenhancement research, it will require further elaboration and refinement as it faces a series of challenges in application, such as setting boundaries on acceptable research efforts and establishing appropriate oversight.

Finally, in ▶ Chap. 74, "Brain Research on Morality and Cognition" Debra J.H. Mathews and Hilary Bok describe yet another dimension of human brain research and ethics that explores the very basic nature of human morality and cognition. Although a range of approaches from the social sciences have been used in this way, Mathews and Bok rely primarily on findings from brain research using fMRI (functional magnetic resonance imaging), examining the potential relationships of these findings to how we make moral decisions. For example, they review a series of studies investigating the role of emotions in responding to moral dilemmas and others assessing the distinction between actions and omissions. In addition, they take notice of a set of studies analyzing differences among psychopaths and non-psychopaths. While the findings from these studies are intriguing, they are necessarily limited for an array of scientific reasons that should be considered carefully before reaching firm conclusions about the nature of human morality. Moreover, findings about how moral decisions are made do not answer the ethical question about what we ought to do. Given such scientific limitations and the recognition of the current ambit of brain research, Mathews and Bok argue that scientific integrity demands appropriate caution when describing the implications of the findings of this research.

In aggregate, the four chapters in this section provide an overview of many of the ethical issues faced in human brain research, providing a taste of the complexity

faced in the field. Further, each of the chapters not only offers important cautions regarding work in the field that merit attention, but they also offer suggestions for addressing related ethical issues as brain research evolves. Future scholarship should be directed at assessing the effectiveness of these suggestions.

burdensome and often invasive strategies? This chapter examines some of the ethical and social dimensions of translating new neurological interventions from laboratory concept into various stages of clinical development, focusing on the dominant ethical and epistemic issues as they emerge (and reemerge) throughout the knowledge production process. It concludes with a brief discussion of several relatively uncharted ethical and epistemic questions as they pertain to CNS clinical translation.

Introduction

The entire trajectory of neurological research – from preclinical to clinical testing – is rife with uncertainty and risk. Despite the abundance of new molecular targets, therapeutic platforms, and increasingly sophisticated theories of pathophysiology, drug development in neurology remains a failure-prone endeavor. In more than one analysis, translation of drugs that target central nervous system (CNS) disorders has the second lowest success rate of any medical domain (Kola and Landis 2004; Pangaloss et al. 2007), and neurological drug developers can point to an ever-expanding casualty list of promising CNS drug candidates that did not make the grade when put to rigorous testing (e.g., NXY-059 for stroke, semagacestat for Alzheimer's, GDNF for Parkinson's).

This risk, and its reciprocal opportunity, is thick with ethical and epistemic challenges. Given the low likelihood of demonstrating clinical utility and the devastating impact of neurological disease (neurological diseases account for approximately 11 % of disability-adjusted life years in high-income countries, cf. WHO 2006), what neurological interventions should be investigated? What level of evidence provides a warrant for exposing nonhuman animals and human beings to burdensome and often invasive strategies?

This chapter examines some of the ethical and social dimensions of translating new neurological interventions from laboratory concept into various stages of clinical development, focusing on the dominant ethical and epistemic issues as they emerge (and reemerge) throughout the knowledge production process. It concludes with a brief discussion of several relatively uncharted ethical and epistemic questions as they pertain to CNS clinical translation.

Ethical Foundations of Clinical Research

Before proceeding, it is important to establish some of the foundational principles governing clinical translation – and some of the distinctive ways CNS drug development threatens the satisfaction of each. From where, precisely, do ethical challenges in CNS drug development stem? What, precisely, is at stake in the way we conduct and organized clinical development in neurology?

Human Subjects

By far, the most visible and regulated source of concerns cluster around the personal interests of human research subjects. Clinical development requires experimenting on human beings. These experiments threaten the welfare of subjects in several ways. The primary aim of trials is not to provide direct benefit to patients, but rather to produce generalizable knowledge that can change the beliefs and practices of physicians and public health systems. Many burdens borne by subjects are thus not primarily aimed at advancing their personal interests, but rather interests that are external to the human subject. Trials furthermore place patients in the hands of clinical investigators whose loyalties are divided between the needs of the individual patients and the goals of scientific understanding.

More fundamentally, some argue that human research is “dehumanizing” or fundamentally degrading in that it treats human being as manipulable biological objects (Jonas 1969). The principles governing human research, which are laid out in the Belmont Report (1979), the Declaration of Helsinki (2011), and several other policies, aim at providing a road map to promoting the social good of research while still protecting the rights and interests of human subjects. In particular, three core principles are widely viewed as governing the protection of human subjects: respect for persons, beneficence, and justice.

CNS translation poses distinctive challenges for designing research in accordance with all three principles. However, it presents particular problems for respect for persons. This principle states that, when patients have decisional capacity, informed consent must be obtained prior to enrollment in a study. Yet many CNS disorders implicate the very organ of decisional capacity. Trials of new CNS drugs must often enroll subjects who either lack capacity or whose capacity may be declining over the course of the experiment.

The majority of human protection policies accommodate research on individuals lacking capacity. For example, the US Federal regulations for protecting human research subjects acknowledge that these vulnerable individuals require “additional safeguards” and proxy consent (45 CFR 46). However, the content of these safeguards and the legal authorization of proxies are not spelled out in any detail. To ensure that these subjects are respected, some authors have proposed the pediatric standard, where research burdens must not exceed minimal risk (Karlawish 2003; Weijer and Miller 2004).

Unfortunately, the minimal risk standard imposes a serious restriction on the acceptable research procedures in CNS drug development. The brain is difficult to access, owing to the blood–brain barrier and anatomical structure, and many neurological diseases are associated with placebo effects. As a consequence, delivery of interventions and/or internally valid study designs often requires approaches, like neurosurgery, sham procedures, lumbar punctures, or exposure to burdensome co-interventions like immunosuppression. Many such procedures are much more than minimally burdensome and nontherapeutic – and are hence impermissible for patients lacking decisional capacity under the pediatric standard.

Integrity of the Research Enterprise

While the three core principles of research ethics apply to many of the issues in CNS drug development, they are not sufficient to protect all of the parties and interests implicated in or affected by clinical translation. Study design, implementation, and reporting should also safeguard the ability of research systems to supply credible, valid, reliable, and accessible evidence to healthcare and public health (London et al. 2012).

One threat to this goal is the high failure rate for new CNS drugs entering clinical translation – especially those addressing neurodegenerative diseases. These failures exact a potentially unjust drain on public research resources. Another perennial threat is the emergence of medical strategies from outside the mainstream of medicine. Because of the very morbid course of many neurological diseases, patient groups sometimes clamor for testing of approaches that lack a firm scientific foundation. Examples include venous angioplasty for multiple sclerosis (Zamboni et al. 2012), use of "patterning" for neurologically impaired children (Ziring et al. 1999), various nonvalidated "stem cell" approaches (cf. Braude et al. 2005), or intravenous immunoglobulin for Alzheimer disease (Schott and James 2012). Although patient subjects may perceive these treatments to be in their best interest, thorough testing of such heterodox therapies expends the limited human and material resources and may mean that development of more promising treatments is delayed.

More generally, just and efficient allocation of research resources remains a somewhat underexplored ethical issue: How should researchers select new candidate therapies for human testing? How rigorously should each candidate be evaluated before it is either advanced into later phases of research or abandoned entirely? The lack of proven effective therapies for many CNS disorders, and the considerable expenses associated with their development, amplifies the need for principled answers to these questions (Hey and Kimmleman n.d.).

Animal Welfare

Neurological translation also requires extensive experimentation on animals, which have moral status. Experiments used in neurological translation are harmful – and often highly morbid. Experiments testing drugs aimed at treating pain must induce pain states in animals; drugs aimed at treating traumatic brain injury start by causing brain injury in animals that have brain anatomies and functions that are similar to human beings. Some commentators (Lafollette and Shanks 1996) question whether any animal experimentation that induces animal suffering for the sake of medical research is ethically justifiable. Other commentators take a less abolitionist approach, viewing its permissibility conditional on variables like limiting human suffering and attainable advances in medical knowledge (Ringach 2011).

Neurological drug development presents distinctive challenges here as well. First, some neurological drugs target disorders that, almost by definition, are conditions of suffering. To develop drugs for diseases like depression, anxiety, or neuropathic pain, researchers must induce depression-like states, anxiety, or neuropathic pain in animals.

Second, many neurological disorders have no clear counterparts in animals. Parkinson disease and Alzheimer disease do not naturally occur in animals. As a consequence, animal models of these diseases have limited value in terms of supporting inferences about clinical utility. This causal disanalogy between the animal experiment and the human trial is a threat to construct validity (Henderson et al. 2013) and renders more fragile the proposition that animal suffering in such circumstances is redeemed by proportionate gains in knowledge.

A third key problem is that, more so than any other drug development area, neurological translation uses animals that have more sophisticated capacity for mentation, e.g., nonhuman primates. This is because many CNS disorders implicate processes – cognition, memory, affect, fine motor skills – that only have counterparts in nonhuman primates. After all, the goal of clinical generalization drives researchers to use animals whose brains have capacities that are as similar as possible to those of human beings. Some commentators draw no moral distinction between induction of suffering in different species (Singer 1990). Others, however, regard higher mentation – for example, capacity for self-awareness – as conferring equal moral consideration (DeGrazia 1999; Weatherall 2006). One set of commentators (Sughrue et al. 2009) explicated what it would entail to extend moral consideration to nonhuman primate stroke studies and concluded that such studies are, in principle, ethically justifiable. But regardless of how one resolves this problem, policies generally extend more stringent protections to animals that have more humanlike mental capacities (several jurisdictions ban all invasive chimpanzee studies, cf. Wadman 2011; the US Institute of Medicine recently issued a report spelling out restrictive criteria for such research cf. Committee on the Use of Chimpanzees in Biomedical Behavioral Research 2011).

A last controversy in CNS research is the creation of human-animal chimeras through neural tissue grafting. Various research efforts aimed at understanding brain function have involved grafting of human neural tissue into the brains of animals – including nonhuman primates. Here, the concern is: Do chimeric animals "acquire" human moral status by virtue of the grafts? If so, is there something transgressive or problematic about bestowing moral status in this way? And ought beings that have acquired humanlike capacities be provided humanlike protections?

To some extent, the answers to these questions hinge on scientific issues. In general, emergence of humanlike traits is a greater concern only where transplantations occur early in brain development, involve large amounts of tissue into more humanlike species (apes as opposed to monkeys), and where tissues are transplanted into brain regions involved in higher brain function (Greene et al. 2005). Whether there is something problematic about bestowing humanlike traits will largely hinge on whether this leads to suffering. Some commentators entertain

the prospect that acquisition of higher brain function could, in principle, lead to flourishing (Ibid.), and at least according to the "equal consideration" view (cf. DeGrazia 1999; Weatherall 2006), nonhuman primates that have acquired humanlike brain functions should be accorded protections similar to those of human beings. The problem, as one commentator points out, is that a laboratory setting, which gives rise to this acquired moral status, is precisely the setting where treatment of the chimera is unlikely to accord with moral principles (Streiffer 2005).

Having surveyed foundational principles governing clinical translation, we now turn to a discussion of key issues arising as interventions are advanced from laboratory conceptions into validated clinical products.

Preclinical

Preclinical testing, which consists of toxicology studies and proof of principle ("animal efficacy studies"), is the first step in transforming laboratory discoveries into clinical application. Well-designed, executed, and reported preclinical studies provide the evidentiary grounds that anchor the ethical basis for launching clinical investigations. Toxicology studies can establish reasonably safe starting doses for first-in-human trials, and they can help researchers to anticipate and manage common toxicities. Efficacy studies provide the rationale for clinical development. Because the clinical utility of new interventions is often not tested until phase 2 trials (see below), the evidence in preclinical efficacy studies must support not merely the first-in-human studies, but all human investigations preceding decisive, "confirmatory" trials (i.e., trials that establish the basis for regulatory approval). Preclinical studies further enable researchers to interpret failed attempts at translation. Clinical trials whose outcomes are discordant with preclinical studies are much more amenable to meaningful interpretation when the former have been well designed, executed, and reported (Kimmelman 2009).

To fulfill the aim of protecting human subjects in subsequent trials, redeeming the sacrifice of animals, and marshalling limited research resources towards the advancement of knowledge, preclinical studies should be designed, executed, and reported in ways that support reliable inferences about an intervention's clinical utility. This obvious proposition, however, runs up against various problems with the way preclinical research activities are currently organized.

For instance, preclinical studies are not held to the same standards of design rigor as typical clinical studies. Whereas drug regulators like FDA hold clinical trials to very stringent quality requirements, drug regulators do not, as a rule, carefully scrutinize preclinical efficacy studies when authorizing clinical development (US FDA 2006). Moreover, ethics review committees, too, are rarely qualified to assess the preclinical studies underwriting clinical development programs. Institutional Animal Care and Use Committees, which review studies for animal welfare, are not empowered to provide stringent review of preclinical studies for their clinical generalizability. As a consequence, investigators and sponsors have

a very wide discretion about the design, execution, and interpretation of preclinical efficacy studies.

In part, because so many CNS drugs that show activity in animals fail clinical development, the neurology translation community has been at the vanguard in addressing sources of bias that may lead to spurious preclinical findings (cf. van der Worp et al. 2005, 2010). These sources fall into four broad categories: First, many preclinical studies do not implement measures to address threats to internal validity, such as randomization and concealed treatment allocation. Second, studies often use deficient representations of human disease or treatment – i.e., a lack of construct validity (Henderson et al. n.d.). As described above, many human neurological illnesses – Parkinson disease, Alzheimer disease, Huntington disease – have no natural counterpart in animals. But other limitations with construct validity are less insuperable. For instance, new drugs are rarely tested in animals that suffer from comorbidities common in human neurological illnesses, even though in some instances, such comorbidities appear to modulate the activity of new drugs (Bath et al. 2009). Interventions are often implemented in preclinical studies that are flatly impractical in trial settings. For instance, drugs for treating stroke must be effective when delivered hours after an ischemic event. However, animal studies often deliver drugs on unrealistic timelines, or they do not run sufficiently long to judge the durability of response (van der Worp et al. 2005).

A third common problem concerns the “external validity” of studies – their capacity to demonstrate that the causal properties of new interventions extend to various untested conditions. In recent years, numerous reports have surfaced documenting problems and deficiencies with replication, quasi-replication, and other attempts to reproduce causal relationships using different methods (Mullard 2011; Begley and Ellis 2012). In Alzheimer disease, for example, early animal studies showed promising results for therapies that targetted the protein fragment amyloid-β, which is known to form plaques in the brains of Alzheimer patients. However, doubts were soon cast on the efficacy of this approach after human trials failed to reproduce the success seen in the animal model, and subsequent animal experiments were unable to ever replicate the early positive finding (Ledford 2010).

A fourth common problem in preclinical research is that it is often not well systematized and aggregated. This reflects a cluster of related problems. For one, systematic reviews are uncommon in preclinical research (Sandercock and Roberts 2002), and as a consequence, human clinical trial brochures, which describe the merits of a proposed study to the ethics review board, do not always capture the totality of relevant evidence. Second, laboratory practices in preclinical research vary widely. This is partly a strength of the research enterprise, because it allows researchers to sample a wide array of conditions and circumstances in their experiments. However, it greatly complicates the process of synthesizing preclinical evidence. In recent years, various commentators have proposed standardizing some of the methods used to perform preclinical research in CNS translation. Many of these proposals are aimed at addressing the three validity threats described above. However, some propose going further by standardizing the animal models and study designs used across different translation efforts (Ludolph et al. 2010; Perel et al. 2007).

Closely related to the design and execution issues canvassed above is the problem of reporting. Underreporting – particularly underreporting of unfavorable or negative findings – occurs in three broad ways. First, researchers sometimes censor their data. For example, animals that show anomalous effects in preclinical studies will often be excluded from the analysis. Second, researchers sometimes opt not to publish their results at all. Study after study has used statistical methods to demonstrate that preclinical efficacy studies in neurological disease are often underreported – and this under reporting biases against negative or null studies (Wheble et al. 2008; Sena et al. 2010). Third, often researchers publish studies but provide very little information about how studies were performed. For example, sample sizes or error bars might not be included in figures (van der Worp et al. 2010).

To some degree, such reporting practices are defensible. Experimental findings have asymmetric epistemic properties where methodologies are not yet well established: Positive treatment effects often have a relatively clear explanation and can be regarded as informative, whereas null or negative results can have myriad plausible explanations and are often not informative at all. For instance, negative results can reflect implementation errors in an experiment, or flaws in design or method, or a general failure to tap into the right causal system. Further to this point, the incentive structures that operate in preclinical research disfavor publication of negative findings. Preclinical research is often conducted in the private sector, where trade secrecy or confidentiality agreements discourage transparency. Even where preclinical studies are performed in academic settings, researchers are not rewarded professionally for publishing negative studies.

Various remedies have been proposed, as for example, guidelines for design of CNS preclinical efficacy studies (STAIR 1999; Fisher et al. 2009; Kilkenny et al. 2010). Other proposals aim at rewarding negative publication, including the establishment of journals that are chartered to publish negative or inconclusive findings (e.g., *PLoS One* or *The All Results Journal*), new methods for systematic review that enable statistical "correction" for underreporting, and establishment of registries and data repositories for preclinical studies (Kimmelman and Anderson 2012). Nevertheless, a crucial challenge here is that improving the protection of human subjects and the clinical research enterprise through better preclinical research may require greater commitment of resources to the latter – and still greater burden on animals. How these burdens and costs in human testing ought to be weighed against those in animal research activities is far from resolved.

Early Phase and Hypothesis Exploration

Clinical development begins with first-in-human trials and extends into other kinds of human trials, including dose-ranging studies, proof of principle studies, biomarker investigations, and preliminary tests of efficacy (e.g., so-called "phase 1" and "phase 2" testing). This stage of clinical translation is generally aimed at exploring and constructing discrete, testable hypotheses concerning clinical utility that can be put to rigorous testing in large, late phase trials.

Early phase studies represent the point of maximum uncertainty concerning the properties of a new intervention. Some of these uncertainties are quantifiable – and significant. For example, the overall risk of permanent or serious neurological deficits due to neurosurgical procedures for delivering agents to deep nuclei in Parkinson disease trials is on the order of 0.8 % (Kimmelman et al. 2011). However, many uncertainties are less bounded in CNS drug development. As previously indicated, some CNS functions – e.g., cognition or affect – are difficult, if not impossible, to model in animal systems. Brain derangements are often irreversible and may not be apparent immediately after receiving an intervention (Duggan et al. 2009).

These uncertainties, which present fundamental problems for protecting subjects and the integrity of the research enterprise, confound two closely related ethical questions: First, how much and what kind of evidence is sufficient to launch human investigations? One proposal is the "principle of modest translational distance," according to which, initial tests in human beings should be scaled and staged according to the levels of uncertainty concerning the biological properties of an intervention (Kimmelman 2009). This means that, where there are significant uncertainties about the pharmacokinetics and pharmacodynamics of a new strategy, initial human investigations might use very limited exposures to a new intervention to nail down one set of variables before advancing to research activities testing safety and efficacy in larger populations. Ultimately, the question of when to initiate human trials is entangled with the intractable problem – discussed below – of what counts as an acceptable risk/knowledge-value balance and how this balance can be improved.

Second, how does one justify exposing volunteers – often cognitively compromised ones – to substantial nontherapeutic risks and burdens with little assurance of therapeutic benefit? Risks of clinical research can potentially be justified by appeal to therapeutic value for subjects or the social value of the knowledge that is expected to accrue from the study. As we will see below, in late phase studies, administration of unproven drugs is supported by evidence of clinical utility from earlier phase studies and hence can credibly claim competitiveness with standard of care. However, such therapeutic justification for risk exposure in early phase studies is suspect on the grounds that, at the stage early phase trials are run, researchers rarely know precisely how to combine the drug with various material and cognitive practices in order to unlock its clinical utility (Kimmelman 2012). Further, low base rates of successful translation suggest that the prior odds that any one CNS drug candidate will have clinical value at the outset of early phase testing are exceedingly small (Kimmelman and London 2011). As a consequence, the ethical justification for administering new CNS interventions in early stages of clinical translation should generally be grounded in knowledge value.

This nontherapeutic orientation of intervention administration in early phase studies has implications for numerous aspects of trial design and conduct, beginning with subject selection: Should trials enroll patients early in a disease process or only after their condition has advanced? Some favor the former, because many interventions are designed to intervene in early stages of neurodegeneration and as such, hold little prospect for benefiting patients in later stages (Lowenstein 2008).

However, patients with recent onset disease are often candidates for other care options or may have a relatively high quality of life. Exposure to untested drug candidates has potentially large opportunity costs for them – especially where neurosurgical procedures are involved.

If the prior odds of clinical utility are low at the outset of investigation, an intervention should initially be tested in patients who will experience lower opportunity costs – namely, patients with advanced disease. However, given that disease might have progressed beyond the window where therapeutic strategies are useful, and that comorbidities will often be present with advanced-disease subjects, this can frustrate the studies' capacity to detect signals of clinical utility and thus adequately to address a key research question for early phase studies.

For informed consent, patients with advanced disease may have exhausted standard treatment, and research has consistently demonstrated that many such patients enter early phase studies primarily motivated by the prospect of therapeutic benefit. Informed consent procedures should strive to explain to subjects that their trial enrollment is unlikely to benefit them medically and is, in fact, more likely to entail burdens. Notwithstanding widely expressed views in bioethics to the contrary, there are grounds for believing that patients often understand the nontherapeutic orientation of research in spite of harboring therapeutic motivations (Kim et al. 2009; Sulmasy et al. 2010; Weinfurt et al. 2008).

The nontherapeutic risk justification for intervention administration in early phases also has implications for many trial design features. Consider the question of whether to randomize patients to new drug on a 1:1 or 2:1 basis, favoring the experimental intervention. Many neurological early phase trials use the former (cf. Cudkowicz et al. 2003, 2006). However, 2:1 randomization requires a larger sample size to attain the same statistical power and therefore exposes greater numbers of subjects to a new and untested agent (Pocock 1979). All else being equal, the principle of risk minimization would favor designs that enroll the fewest patients and hence would discourage use of 2:1 randomization schemes.

Finally, there is the problem of how one designs early phase studies that will produce knowledge sufficient to redeem the burdens and risks of nontherapeutic exposures. There are three ways that early phase trials might produce a gain in knowledge: The first is if the trial produces information that leads to successful translation of the intervention. However, as discussed above, the probability of this kind of knowledge accruing is exceedingly low for many neurological disorders.

A second kind of knowledge is gained if the trial rules out an intervention for further testing, such that research efforts can be redirected toward other therapeutic strategies. Given the high failure rate for new CNS drugs entering clinical testing, the probability of this type of knowledge accruing is high (Kola and Landis 2004). However, if the research community is contemplating a large number of other strategies, the *relative value* of this knowledge is low, since all that is learned is that one of a large number of candidate strategies is not useful.

The third kind of knowledge concerns hypothesis formation and evaluation – in this case – pharmacological or pathophysiological knowledge gained in a study. For example, if researchers observe that a promising agent modulates an intended

target but fails to induce a therapeutic response, researchers have gained a pathophysiological insight – namely, that the relationship between a drug target and clinical response is at best an attenuated one. This knowledge can then help researchers troubleshoot their intervention, or it can help guide decision-making about other strategies that modulate the same target. This last type of knowledge is quite valuable; however, designing studies to produce pharmacological or pathophysiological insights often necessitates additional research procedures like lumbar punctures or biopsies. As noted above, these additional research procedures may not accord with the principles of respect for persons lacking decisional capacity.

A last set of ethical issues concerns the reporting of early phase studies. Reporting of results is the first step through which isolated observations are integrated into a larger body of knowledge, hence redeeming both the sacrifice of volunteers as well as the resources expended in clinical investigation. Reporting is a crucial step in the chain of accruing generalizable knowledge in all phases of research. However, in contrast with later phases, investigators conducting many types of "hypothesis-exploring" studies are not currently required by federal regulations to prospectively register their studies in a public database. As a consequence, many early phase and exploratory studies go unreported. Publication bias in CNS drug development has been reported (Liebeskind et al. 2006; Psaty and Kronmal 2008; Sanossian et al. 2006), though little is known about whether publication biases are higher in early phase, exploratory, or biomarker studies (for one study that paints a reassuring picture of publication practice in neurology diagnosis investigations, see Brazzelli et al. 2009).

Late Phase

Late phase clinical testing generally consists of large trials that use symptomatic or clinical endpoints to confirm the clinical utility of new strategies. Such studies tend to be multicentered, enroll hundreds (or sometimes thousands) of patients, run for a longer observation periods (e.g., 6 months or a year), and involve randomization to comparator treatments. Many ethical issues encountered in early phase research also present themselves in late phase trials – e.g., the problem of subject selection or the challenges of obtaining valid informed consent. However, ethical issues in confirmatory trials have somewhat of a different character. Where the fundamental ethical challenge in early phases is uncertainty, the key challenge for late phase studies is risk (i.e., a more quantifiable and bounded judgment about the probability of undesirable outcomes).

We noted, previously, that risks in research can be ethically justified either by appeal to direct benefits for the subject or benefits to society. In general, risks of new interventions in confirmatory trials draw on the former justification. Yet the goal of producing reliable, clinically relevant knowledge is still present.

By far, the most hotly debated issue in neurology late phase studies is the choice of comparators. Judgments about clinical utility are always comparative. A drug might

moderate a disease course, but if its activity is less than what patients might otherwise receive in care (or if the drug has a more noxious side-effect profile than the alternative), it may still fall short of clinical utility. Accordingly, all trials aimed at demonstrating clinical utility necessitate comparison. In neurology confirmatory testing, comparators are almost always included as an arm of a trial. This is because neurological disorders often have waxing and waning disease courses, endpoints involve subjective measures like functional improvement, and some disorders (e.g., Parkinson disease) are associated with large and durable placebo effects. Though the need for internal comparators is widely accepted, their choice can be controversial.

Many late phase neurology trials use placebo comparators. Under the principle of clinical equipoise – which holds that no patient in trials receives less than standard of care (cf. Freedman 1987; Weijer et al. 2000) – placebo comparators are only ethical where there are no validated care options, where withholding standard of care entails only minimal risk, where patients have opted to decline standard treatments in the course of clinical care, or where justifiable and insuperable material constraints severely limit the supply of an intervention. For example, riluzole is the only validated treatment for amyotrophic lateral sclerosis (ALS), but since its clinical utility is marginal, many ALS patients choose not to receive it. Placebo-controlled trials of ALS can be ethical if they recruit such patients. However, many trials involving neurological disorders use placebo comparators, even though doing so entails that some patients will be deprived of effective treatment (Polman et al. 2008). Such trials violate the principle of clinical equipoise, and because they do not test new treatments head-to-head against standard care options, their results do not provide the kind of comparative information healthcare providers need for choosing between the two treatment options.

Another ethical question arises from the use of sham surgical comparators. We previously noted that the brain is difficult to access. Delivery of many CNS interventions therefore involves surgical interventions. For example, trials testing delivery of neurotrophic factors for treatment of Parkinson disease involved implantation of catheters to deep nuclei (Lang et al. 2006). However, surgical interventions introduce a causal confounder into experiments. Neurosurgery, for example, inadvertently lesions tissues or causes inflammatory processes that can interact with disease symptomatology. In addition, symptomatic diseases like depression, pain, and Parkinson disease are associated with large placebo effects (de la Fuente-Fernández et al. 2002). As a consequence, isolating the causal relationship of a new intervention will often necessitate trials where some subjects receive a sham surgery. A discussion of the ethics of sham surgery is deferred to ▶ Chap. 72, “Ethics of Sham Surgery in Clinical Trials for Neurologic Disease”.

Post-licensure

Production of knowledge about an intervention does not end at the point where a product is introduced into the market and taken up into practice. At the point of product licensure, uncertainties still abound.

For example, a prelicensure phase 3 trial might enroll as many as 1,000 or 2,000 patients. However, a two-arm trial would have to enroll at least 7,000 patients to have 50 % statistical power for detecting a 1 in 500 incidence in a drug-related event that otherwise occurs in the general population with a frequency of 1 in 1,000 patients (Eichler et al. 2008). Therefore, pharmacovigilance – monitoring of drug safety post-licensure – is needed to learn more about safety in larger populations.

There may also be uncertainties about a new intervention's utility in populations or settings that are less controlled than those in clinical trials. For instance, are drugs as effective in senior patients? Are they safe in patients with high blood pressure? These patient groups are often excluded from clinical trials, and therefore, questions may remain about the generalizability of trial findings. Finally, there are questions concerning whether new interventions might be useful in related indications – is a Parkinson disease drug useful for essential tremor? Post-licensure research is an essential component of extending causal inferences to unsampled settings.

The major ethical issues arising in post-licensure research are less about risk and uncertainty for volunteers, because most post-licensure studies are performed in ways that cohere with care standards. "Comparative effectiveness" studies, for example, randomize patients to receive one of two approved drugs, where the aim is not to evaluate efficacy but to compare the net therapeutic benefits of each treatment. For these studies, conventional approaches to research ethics – which are preoccupied with protecting the welfare of subjects – may not highlight the most salient moral issues.

Instead, the overarching ethical problems concern the welfare of patients, physicians, and other actors who depend on the knowledge produced in post-licensure investigations (London et al. 2012). On the one hand is the problem of insufficient research oversight. Unlike prelicensure trials, drug regulators have very little leverage over drug companies concerning the design, implementation, or reporting of post-licensure trials. And because post-licensure investigations entail very little risk to volunteers, ethics review bodies often do not vet them carefully for design quality (in the USA, their regulatory mandate is to evaluate knowledge value against risk to subjects, not to evaluate knowledge value against some other social standard, cf. US DHHS 45 CFR 46). As a consequence, post-licensure trials are occasionally performed or reported in ways that are suspect. This dynamic was readily apparent in the case of the epilepsy drug gabapentin, where litigation revealed that reporting of post-licensure trials was selective and skewed in favor of the drug (Vedula et al. 2009, 2012).

On the other hand is the problem of unduly onerous oversight. Increasingly, public funders, insurers, and healthcare systems are supporting post-licensure, comparative effectiveness trials in non-research settings. In neurology, these trials have looked at such questions as whether carotid stenting performs better than endarterectomy for preventing stroke (Brott et al. 2010). These studies are critical for healthcare systems, because practitioners in non-research settings often perform

differently than their researcher counterparts, and case mixes in practice settings are much more medically diverse than those in research. Moreover, such studies are useful for assessing the cost-effectiveness of treatment strategies.

Comparative effectiveness research often involves practically no departure from care, other than randomized allocation and transfer of medical chart information into a database. Under conventional accounts of research ethics, the fact of randomization would necessitate full independent review, as well as a cumbersome informed consent process. The transaction costs and layer of oversight add substantial logistical, financial, and temporal burdens for comparative effectiveness studies. Some commentators are urging a more permissive approach to comparative effectiveness research (cf. Vickrey et al. 2012). How, precisely, these proposals will promote the social good of comparative effectiveness and pharmacovigilance studies without inadvertently inviting more of the kinds of seeding studies described above remains to be determined.

Conclusion and Frontiers

Many of the ethical and social issues we have discussed pertain not only to new neurological candidates but to all domains of drug development. The shifting of uncertainty to risk as research moves from early to late phase, the need for higher standards in preclinical reporting, and the use of placebo comparators in place of proven, effective treatments – these issues are confronted in many domains of drug development. Nevertheless, translating new neurological interventions from the bench to the bedside does present a distinctive cluster of challenges: The very low base rate for the success of a new drug places extra strain on the preclinical and early clinical phases of development to ameliorate as much uncertainty as possible in advance of human testing. Reduced patient capacity introduces additional complications to the issues surrounding informed consent and subject selection. The invasiveness of some research procedures and delivery approaches presses against long-held views that patients – especially patients debilitated by illnesses that compromise decisional capacity – ought not to be exposed to risky manipulations that lack therapeutic warrant.

While the standard ethical frameworks – built upon the principles of respect for persons, beneficence, and justice – may not definitively resolve these issues, they nevertheless provide a foundation for argument and refinement of CNS research policies. However, there are many other issues concerning the integrity of the research enterprise that are not as well worked out. These include questions about priority setting in clinical development, better protecting parties that draw on knowledge produced in translation, and oversight of post-licensure studies. Here, the standard frameworks for research ethics may not highlight the most salient moral concerns. The risks and uncertainty that persist across all phases of CNS drug development and beyond underline the importance and need for extending and elaborating ethical frameworks to address these problems.

Ethics of Sham Surgery in Clinical Trials for Neurologic Disease

72

Sam Horng and Franklin G. Miller

Contents

Abstract

Controversy over the use of sham surgery has evolved over the last decade. Initially rejected by many bioethicists due to concerns over the level of risk involved and the presumed low prospect of benefit, the use of sham controls has gradually become a standard practice in the mainstream of neurologic clinical trial design. The evolution of these attitudes and the ethical arguments in favor of sham surgery in clinical trials for novel neurologic interventions are reviewed in this chapter, with emphasis on prominent trials in the field of Parkinson disease research. A practical framework for the ethical assessment of sham neurologic

The opinions expressed are those of the authors and do not necessarily reflect the position or policy of the National Institutes of Health, the Public Health Service, or the Department of Health and Human Services.

procedures is provided, with special concerns pertaining to the cognitive limitations, as well as functional measures used, in populations with neurologic disease.

Introduction

The use of sham procedures, including sham surgery, in clinical trials once raised strong ethical objections, particularly in the setting of Parkinson disease (PD) and the administration of intracranial therapeutics (Macklin 1999; Gillet 2001; Albin 2002; Freed et al. 2001). Many ethicists argued that sham surgery posed an unacceptable level of risk with no counterbalancing prospect of clinical benefit (Weijer 2002). Moreover, sham controls were judged to violate the Hippocratic tenet of “do no harm” (Macklin 1999). These arguments, however, conflated the goals of medical practice with those of clinical research (Horng and Miller 2002). When methodologically necessary, the use of placebo procedures has repeatedly demonstrated the importance of controlling for the expectation effect, a significant therapeutic response that is due to expectation alone (Katsnelson 2011). In the field of PD research, a number of promising novel interventions have been shown through sham controls to contribute no more than placebo to significant clinical improvements (LeWitt et al. 2011; Marks et al. 2010; Gross et al. 2011; Lang et al. 2006). In fact, because of these data, placebo controls have been embraced within the PD research community as an ethically acceptable and methodologically necessary gold standard of clinical trial design (Katsnelson 2011).

The debate of sham surgery was sparked by early experiments using a sham control for the intraputaminal injection of fetal dopaminergic stem cells of PD patients (Freed et al. 2001). Two dueling Sounding Board articles in the *New England Journal of Medicine* argued alternately for the methodological necessity of sham controls and the unacceptability of their risk (Freeman et al. 1999; Macklin 1999).

Throughout the following decade, additional placebo-controlled trials in the PD field, including two gene transfer studies, a cell transplantation trial, and a GDNF infusion trial, demonstrated the importance of a sham control as negative results tempered promising positive data from prior open-label trials (LeWitt et al. 2011; Marks et al. 2010; Gross et al. 2011; Lang et al. 2006). Furthermore, a growing body of placebo-controlled data in a diverse array of other fields has exposed the clinical inefficacy of internal mammary artery ligation for angina, arthroscopic knee surgery for osteoarthritis, and vertebroplasty for pain from vertebral fractures (Beecher 1961; Moseley et al. 2002; Miller et al. 2011).

Placebo controls are important especially in neurology and neurosurgery for several reasons. Outcome measures may involve symptoms assessed with subjective rating scales, including pain, headache, fatigue, mood, cognition, and mobility. A placebo is often necessary to control for the reporting effects of expectation bias. Even seemingly objective measures can be affected by expectation. In PD, for

example, measures of mobility may be subject to bias from both the evaluator and the patient: When patients expect benefit from an intervention, they may be motivated to manifest improved performance. Finally, expectation itself may modulate neurologic function as demonstrated in an emerging body of literature on the placebo effect in a range of diseases, including Alzheimer disease (AD) and PD (Alterman et al. 2011; Benedetti et al. 2006). Belief itself in the therapeutic effect of an intervention has been shown to effect quantitative measures of function, including patterns of brain imaging as well as muscle tone (Benedetti et al. 2005).

Furthermore, neurologic disease can affect cognitive processes which may in turn augment or decrease the placebo effect, requiring a placebo arm to reliably extract the role of expectation from intervention effects. For instance, AD patients with frontal lobe dysfunction have been shown to have diminished expectation-related effects of analgesia in contrast to those with temporal parietal occipital dysfunction alone, who show an intact placebo response (Benedetti et al. 2006). Without a placebo control, one would falsely conclude that analgesia is effective in only those patients with temporal parietal occipital dysfunction, whereas, in truth, the patients with frontal lobe dysfunction have lost the capacity for a positive expectation effect.

Methodological concerns and practical trial design (i.e., shortening trial length and small enrollment) so strongly favor the use of a placebo that it is currently the accepted gold standard in the field of PD, where clinical trials involve the most invasive of placebo control designs: 94 % of investigators approve of a sham control, although only 20 % advocate for higher risk sham procedures involving dural penetration (Kim et al. 2005). Research subjects in these trials also understand the rationale for placebo and demonstrate a deliberation process accounting for risks and benefits when deciding to participate (Kim et al. 2012).

In this chapter, guidelines for assessing the justification of a sham procedure or surgery in a neurological or neurosurgical trial are provided. A survey of research demonstrating the importance of the placebo effect in outcomes of neurologic disease is started with. Next, an ethical framework for the use of a placebo arm is reviewed. Finally, special considerations are examined in the subject populations involved in clinical trials of neurologic disease, particularly neurodegenerative disorders raising questions of competency and decision making.

The Placebo Effect and Neurologic Disease

The justification for the use of invasive sham procedures in evaluating treatments for neurologic disease should be framed within the larger context of clinical research ethics. The goal of clinical research ethics entails the production of useful knowledge that will advance the care of future patients (Emanuel et al. 2000). This goal is held in contradistinction to that of clinical care, which is to optimize the care of an individual patient being treated (Horng and Miller 2002). Concerns over the excessive risk posed by placebo surgery should arguably be considered under a framework specific to the goals of research and not clinical care (Litton and Miller 2005).

In order to ensure that the future implementation of an experimental procedure or neurosurgery would provide benefit to patients without imposing excessive risk or financial cost, a placebo control is often necessary to avoid several sources of false-positive error: (1) bias by unblinded outcome assessors, particularly for outcomes using a subjective rating scale, (2) report bias from the subjects who know what intervention they have received, (3) effects of expectation on outcomes, whether subjective ratings or quantifiable measurements, and (4) confounding effects from any additional factors not attributable to the hypothesized mechanism of the intervention under investigation. In most trials using sham invasive procedures, it will be impossible or unsafe for the physician-investigators performing the procedure to be blinded to the intervention administered; however, those researchers who assess outcomes should be blinded.

Therapeutic outcomes of neurologic disease often include symptoms assessed with subjective rating scales, such as pain, depression, headache, fatigue, quality of life, and mobility/motor function. Expectation can also influence seemingly objective measures such as exercise tolerance or motor function. Finally, quantitative measurements may also be influenced by expectation effects, if a placebo intervention exerts biological effects and modulates the neurologic processes underlying symptoms of the disease.

For example, multiple placebo-controlled trials of acupuncture demonstrate a placebo effect for analgesia, as determined by comparison of the sham acupuncture to a no treatment control, of around 33 % (Horng and Miller 2007). Sham arms for various gene transfer and cell implantation therapies in PD patients revealed improvements in motor function ranging from 13 % to 48 % (Katsnelson 2011). This effect is usually attributed to the placebo effect, although other factors may contribute to observed improvement after receiving a sham intervention. To our knowledge, there have been no sham surgical trials to date with a "no treatment" control group, which would be needed to more precisely assess the improvement that can be attributed to the placebo effect.

Placebo interventions have been shown to modulate a diversity of brain processes, including blood flow to regions of pain processing in healthy subjects given painful stimuli, increased putaminal dopamine release in PD patients, and decreased subthalamic nucleus activity correlating with improvements in motility in PD patients (Wager et al. 2004; Benedetti et al. 2004; De la Fuente-Fernandez et al. 2001).

Expectation may also exert biological effects under "operant conditioning" paradigms, where repeated administrations of an active intervention paired with an inert stimulus induce by association an active response to the inert stimulus over time. Experiments have shown that cyclosporine paired with a flavored drink has been shown to induce a conditioned immunosuppressive response to the flavored drink alone (Goebel et al. 2002). It is conceivable that patients with neurologic disease have similar conditioned therapeutic effects to nontherapeutic aspects of the clinical milieu in research trials.

Finally, nonspecific effects of a therapy such as tissue lesions secondary to electrode placement for deep brain stimulation in epilepsy, PD, or dystonia may

exert therapeutic effects that are optimally controlled under sham conditions (Andrade et al. 2006; De la Fuente-Fernandez et al. 2002). These possible effects would be incidental to the properties of the experimental treatment under investigation and not related to its hypothesized mechanism.

In sum, without a sham control, the expectation effect, as well as investigator and subject biases, may contribute to observed therapeutic effects misattributed to the novel intervention. Especially in placebo-responsive conditions with few treatment alternatives, biased outcome assessment may lead to the erroneous adoption of novel interventions that lack treatment-specific efficacy into standard clinical care, thereby subjecting patients to false claims of benefit, undue risk, and unnecessary financial cost. In fact, invasive procedures are often incorporated into clinical practice without prior rigorous evaluation, owing to weaker US FDA standards (Horng and Miller 2002). There are currently no FDA requirements for surgery unless medical devices are used. Nonetheless, the FDA recently warned patients about the risks associated with a novel extracranial venoplasty and stenting procedure for multiple sclerosis, which has yet to demonstrate proven benefit in randomized, placebo-controlled, double-blinded trials (Kuehn 2012). The controversy over this emerging procedure illustrates the growing concern over rigorous efficacy testing of risky surgeries prior to acceptance into the clinical standard of care.

Ethical Concerns in the Use of Sham Procedures in Neurologic and Neurosurgical Trials

A critical factor in the ethical assessment of sham surgery is the level of risk posed to subjects. Sham pharmaceuticals offer uniformly minimal risk from the procedure itself, although they do pose the risk of withholding treatment when proven effective treatments exist for the condition under investigation. Sham procedures, on the other hand, carry the risk of withholding treatment as well as the additional risk of the procedure itself, which may vary widely along a spectrum. Prior discussions have outlined this spectrum within the field of neurology and neurosurgery and will be reviewed briefly here (Horng and Miller 2007). Trials will require a careful case-by-case evaluation of the risk-benefit ratio of both the active and sham interventional arms (London 2006).

At one end are minimally invasive procedures such as transcranial magnetic stimulation (TMS), radiation, and acupuncture. TMS involves the delivery of magnetic pulses noninvasively to the cortical surface, which decreases cortical excitability. It has been tested in motor function after stroke, as well as depression and epilepsy (Fregni et al. 2006a, b; Sole-Padulles et al. 2006). The sham control consists of noninvasive coil placement and directing of pulses away from the skull. Sham radiation for metastatic brain cancer would similarly involve a noninvasive absence of treatment. Sham acupuncture for any wide variety of painful conditions, including migraine, also presents minimally invasive risk (Linde et al. 2005).

At the other end of the spectrum are invasive procedures in the critical care setting, for example, intracranial vascular bypass surgery or decompressive craniectomy, which may pose risk of great harm and where the risk of no treatment may be high. For intracranial aneurysms at imminent risk for rupture, an artery ligation and laser perforation procedure offers the prospect of bypass with correction of the aneurysm and avoidance of distal vasculature clamping, which poses a risk of ischemia (Grady 2006). Here, the risk of a sham arm would be excessive, as subjects would be subjected to craniotomy and denied intervention for an emergent, life-threatening event. Similarly, decompressive craniotomy for intracerebral hemorrhage is offered to patients at imminent risk of brain herniation. These critically ill patients are at risk of decompensating during the procedure, and, therefore, a sham control would pose excessive risk in the absence of sufficient prospect of benefit. A sham control for a similar procedure in the absence of this emergency might be acceptable, for example, an elective surgical bypass for moyamoya, a form of intracerebral vascular insufficiency which leads to the progressive accumulation of strokes.

Between the two extremes are more invasive interventions, which uniquely allow patients to participate in both sham and intervention arms using a crossover design, such as deep brain stimulator implantation or intracranial drug infusion. Deep brain stimulation (DBS), which modulates the activity of motor circuits in the basal ganglia, is currently approved for use in essential tremor, PD, and dystonia based on the results of placebo-controlled trials (Kupsch et al. 2006). In these trials, DBS devices are implanted into the brain and subjects are tested sequentially under both ON and OFF conditions. The risks of dyskinesia from aberrant stimulation as well as device infection are counterbalanced by the prospect of direct benefit. Subjects in the OFF condition experience delay in the active intervention but are too spared the risks of such treatment. Nonetheless, if the procedures do not work, an invasive procedure has been performed with no benefit and the question remains what to do with the implanted stimulator. This issue was raised in trials for permanent pacemakers for vasovagal syncope, in which the stimulator ON was no better than the stimulator OFF (Connelly et al. 2003).

Intracranial drug infusion, as has been performed in PD subjects, involves the implantation of an intracranial catheter, which carries risk of infection, hemorrhage, and tissue disruption (Nutt et al. 2003; Lang et al. 2006). Sham arms involve saline infusions but allow for crossover to active drug if benefit is subsequently demonstrated. Despite the invasive nature of the control, the opportunity to receive active intervention if beneficial and the initial non-exposure to potential drug toxicity counterbalances the prospect of delayed benefit and risks of catheter implantation.

Somewhat less invasive but not allowing for participation in both experimental and sham arms are intracranial cell implantations and gene transfections (Freed et al. 2001; Olanow et al. 2003; Bjorklund et al. 2003; Prehn et al. 2006; Frank et al. 2005). In the fetal tissue transplantation trials for PD, the sham arm was exposed to a moderately invasive craniotomy with burr holes into the skull not penetrating the dura. Subjects were also exposed to the risks of an immunosuppressive drug regimen and radiation from PET scans to measure study outcomes.

The modified form of placebo craniectomy has since been adopted in multiple subsequent trials with no reported adverse events (Marks et al. 2010; Gross et al. 2011; LeWitt et al. 2011).

It is important to emphasize that prospect of harm is not a priori greater in the placebo arm. As in drugs, the experimental procedure may pose additional risks not present in the sham interventional arm. For instance, intracerebral infusion of various chemotherapeutic or immunomodulatory agents may cause nausea or vomiting. Whole brain radiation poses the risk of radiation necrosis as well as secondary malignancy. Novel interventions in particular may carry additional unanticipated risks that cannot be quantified. For example, gene transfer carries a theoretic risk of inflammatory and/or autoimmune reactions, end-organ damage, malignancy, or death.

In addition, risk is often minimized in the placebo group by designing a sham procedure that ensures double blinding and, in some cases, promotes or allows for a positive expectation in subjects. For example, in the cell implantation trials for PD as discussed above, avoiding the penetration of the dura allowed for the minimization of risk while simultaneously maintaining the double blind and allowing for a positive expectation.

The risk-benefit ratio may in fact be more favorable in the sham procedure arm, if both the sham and the intervention provide significant, comparable placebo responses and there are adverse side effects avoided in the sham arm. A placebo surgery may conceivably pose a clinically significant prospect of benefit without the fully invasive risks of an experimental procedure. A number of PD trials have demonstrated just these results and have sparked debate over the ethics of providing novel interventions which offer significant clinical benefit but have been demonstrated to offer no additional benefit than placebo in head-to-head comparisons. It is critical to consider distinct risk-benefit profiles for both the experimental and sham control arms that would be deemed acceptable in all possible outcomes of the clinical trial results (London 2006).

An additional ethical consideration involves the use of deception and the adequacy of informed consent in sham-controlled placebo procedure trials. If deception is necessary to maintain positive expectations in both the intervention and control arms, it is imperative to explain to subjects the probability that they will receive a placebo control and that the administration of this control may involve deception (Miller et al. 2005; Wendler 1996). Studies have shown that informing prospective subjects about the use of deception does not bias trial outcomes (Weiner and Erker 1986; Martin and Katz 2010).

Furthermore, willing consent to deception does not compromise a respect for subjects or their ability to make autonomous decisions. Some argue that it is further necessary to debrief subjects after the completion of the trial, although feasibility of debriefing in the setting of longitudinal study designs may conceivably allow for this requirement to be waived (Miller and Kaptchuk 2004).

Data from trials involving sham intracranial cell implantations in PD subjects demonstrate that they do in fact understand the rationale, likelihood, and consequences of receiving a placebo surgery (Kim et al. 2012). The majority of subjects

agreed that this design was ethical despite many hoping to receive the active treatment. Thus, it is possible for subjects to understand, consent to, and exercise their personal preferences in a placebo-controlled surgery trial.

Special Consideration in Neurodegenerative Disease: Competency and Decision Making

Subjects with neurodegenerative disease typically experience decline in cognitive function, which may impair their ability to provide informed consent to placebo-controlled research. Depending on the nature of these deficits, subjects may misunderstand the nature or likelihood of receiving sham surgery, may not fully appreciate or rather downplay the risks involved, or may exhibit apathy or lack of motivation to participate. Therefore, it is critical to account for any cognitive differences that might emerge in the study population with a particular assessment of how risk assessment and motivating behaviors may be affected.

An emerging body of research reveals increases in risk-taking behaviors of PD patients on dopaminergic therapy. In card-sorting games, patients with advanced disease exhibit a decreased ability to optimize profits based on odds learning (Maia and Frank 2011). Clinically, patients on high doses of carbidopa-levodopa often acquire a predilection for gambling and high spending. This aspect of the disease raises concern that this population may be at risk for agreeing to placebo-controlled research that is excessively risky or has an unfavorable risk-benefit ratio.

Conversely, patients with advanced AD may exhibit apathy which may prevent them from being willing to participate in research. Additionally, deficits in abstract thinking may prevent them from understanding a placebo-controlled design. In this way, neurodegenerative diseases may predispose patients to unreasonably either reject or solicit research trial participation.

Processes of cognitive decline may also diminish or potentiate the physiologic effects of expectation. As mentioned earlier, Alzheimer disease patients with frontal lobe dysfunction show reduced analgesic response to placebo compared to those with temporal parietal occipital dysfunction (Benedetti et al. 2006). One might speculate that PD patients, or those with dysfunction of dopaminergic circuits in the basal ganglia experience an enhanced expectation effect. Thus, the degree to which the placebo effect is attenuated or enhanced in a particular population as a part of disease pathophysiology might vary the requirement and design of a placebo control.

An extensive body of literature on research in pediatric populations as well as on individuals with developmental delay explores the vulnerability of subjects who cannot provide informed consent (Wendler 1996). There is a general consensus that these subjects require extra protections, particularly in regard to assessment of capacity, calculation of risk-benefit ratio, and acquisition of consent from parties safeguarding the subjects' best interests (London 2006). Standards for assessment may vary or need to be tailored for those subjects who once had capacity and those who never did.

Among various guidelines, the World Medical Association's Helsinki Declaration recommends that (1) the mental condition is a necessary characteristic of the research subjects, (2) the research cannot be equally conducted on those able to provide consent, and (3) that the study addresses a question pertinent to the population subjected to research (58th WMA General Assembly, Seoul, Korea, 2008). The US National Bioethics Advisory Commission additionally recommends that (4) an independent professional assess capacity if the research involves greater than minimal risk and (5) that subjects refusal to participate should always be accepted (Galpern et al. 2012).

An advantage in patients with cognitive decline is that preferences on research participation may be documented early in the course of disease in the form of an advance directive prior to the onset of deficits, although these documents may not be possible or legally binding in some settings (Berghmans 1998; Pierce 2010). An alternative would be to limit the study to those subjects with the condition who are capable of giving informed consent, though excluding those not capable would then limit a more representative sample. One approach might involve initiating the very early efficacy evaluation with those capable of giving informed consent and then expanding the pool in later phase efficacy testing.

Ethical Framework for Placebo-Controlled Neurological Procedure or Neurosurgical Trials

Drawing from existing guidelines on clinical research ethics and outlined in previous reviews (Emanuel et al. 2000; Horng and Miller 2007), we recommend eight benchmarks in the ethical assessment of a placebo-controlled neurologic procedure or neurosurgical trial: (1) The design of the trial addresses an important, clinically relevant question. (2) The placebo arm is necessary to answer this question and there is no scientifically valid alternative design. (3) The risk of the placebo is minimized consistent with the ability to answer the scientific question. (4) The risks are reasonable in light of the prospect of direct benefit and benefit from the knowledge to be gained. (5) Risk-benefit ratio is assessed independently for both the placebo and intervention arms. (6) If there is no prospect of direct benefit to subjects in the placebo arm, the risks are justified by the benefits to future patients of the clinical knowledge to be gained. (7) Deception is authorized by subjects. (8) Decision-making capacity of subjects is adequately assessed and consent provided by an appropriate surrogate if necessary.

Areas where special deliberation is needed in the specifics of a particular trial include: (1) evidence for a placebo response, especially in populations, such as AD patients with frontal lobe dysfunction, who demonstrate decreased expectation bias, and the necessity of a placebo control, (2) minimizing invasiveness of the sham while maintaining expectation effects, (3) level of risk of placebo procedure, (4) opportunity for crossover into the active arm, (5) level of active deception necessary to maintain expectation bias, and (6) nature of decision-making capacity in the setting of cognitive decline.

Conclusion

Over the last 15 years, the use of sham surgery control groups has become accepted as an ethically sound method of evaluating invasive procedures. The use of sham-controlled trials, particularly in the field of Parkinson disease research, has allowed for the objective demonstration that a number of novel interventions provide no greater benefit beyond a sizable placebo effect. In the ethical assessment of these trials, particular attention is made to the risk-benefit ratio of both the placebo and interventional arms, as well as the use of deception and its authorization. Special consideration must also account for aspects of cognitive decline which may impair prospective subjects' understanding of placebo design, ability to make proper risk-benefit assessments, and willingness to engage in research.

Research in Neuroenhancement

73

Contents

Abstract

In this chapter, we argue that framing neuroenhancement research as not necessarily constituting biomedical or behavioral research, as defined by directly investigating disease or ill health, allows for a more robust ethical analysis. The ethics of this kind of research requires a substantially different description from the one offered by a standard biomedical research ethics model. We propose that neuroenhancement research is better described using a non-biomedical, consumer-based model. Such a conceptual shift would clarify ways in which certain types of enhancement research differ from biomedical research, how risks and benefits ought to be weighed, and how such research might be prioritized in the larger health-related research environment. This approach proposes a framework

for ethical analysis that considers possible benefits of enhancement therapy while acknowledging the limitations of the biomedical research ethics paradigm in this setting.

Introduction

Neuroenhancement research is expansive, involving numerous disciplines and fields of inquiry including medical drugs and devices, educational techniques, dietary methods, external computational systems, and even social networks and forms of shared cognition (i.e., the internet), to name only a few. Given this size and diversity, the ethics of neuroenhancement research contains an appropriately wide spectrum of ethical issues, some more controversial than others. While few would argue against the study of enhancements like the neurostimulant effects of coffee, many raise doubts about genetic, surgical, or pharmaceutical enhancement research and technologies, particularly when these efforts do not target disease or promote biomedical health (President's Council on Bioethics 2003). With these concerns in mind, neuroenhancement research is defined in this chapter to include physical, chemical, or biological alterations of individual persons that are not directed to disease or loss of normal function.

Several ethical concerns relate to the pursuit of neuroenhancement research and technologies. First, neuroenhancement research and technology is new without much precedent for the assessment of benefits and risks. Second, the potential efficacy of these technologies could create problems of access and exacerbate social inequalities. Third, regulatory issues abound with regard to the study and approval of such technologies. Fourth, the long-term consequences for human beings and society are unclear (Bostrom and Sandberg 2009).

These issues are fundamentally related to the structure of scientific research under a biomedical model (Bostrom and Sandberg 2009). Biomedical concepts such as health and disease and related ethical concepts such as informed consent frame ethical analysis in research: How risks and benefits are weighed, which endpoints are selected for efficacy in research, what regulations apply, and how long-term outcomes are monitored. How such concepts can be applied to neuroenhancement research projects raises many questions, many of which fall outside the traditional boundaries of a biomedical research ethics model. This chapter will discuss how the limitations of a biomedical research ethics model require a shift toward a consumer-based model, which protects research participants while allowing for the potential benefits of neuroenhancement research.

Research Ethics and the Neuroenhancement Debate

Discussions about neuroenhancement research ethics are often overshadowed by ethical debates about the permissibility of enhancement technologies more

generally (Juengst et al. 2003). These debates focus primarily on the ethical ramifications of a new enhancement technique or drug. For instance, is it ethically permissible to allow college students to use Ritalin for enhanced academic performance? Should the elderly have access to new drugs to reverse some of the memory-adverse effects of aging? Which substances should competitive athletes be allowed to ingest in effort to improve their performance? However, less attention is devoted to how such interventions ought to be studied, what rules should apply, and who should fund such investigations.

Some critics of neuroenhancement technologies might oppose a discussion of research ethics from the very start (Sandel 2004). If using a drug to improve athletic or academic performance is inherently unethical, then researching its side effects or efficacy profile is moot. Research activities would then only promote an already unethical practice. Other critics argue that enhancement research entails unjustifiable risks to the subjects since there are no "health" benefits to such research to balance the risks (Heinz et al. 2012). Such research is also likely to promote undesirable social consequences by exacerbating existing socioeconomic disparities or creating new disparities between those who are willing to risk their health for the sake of enhancement. Finally, at the very least, enhancement research priorities represent a "luxury problem," which cannot make demands on scarce resources needed for funding health-oriented research (Heinz et al. 2012).

These debates are complicated by the fact that the fruits of neuroenhancement research are already pervasive. Computers expand human storage and analytic capacities' test prep courses and innovative learning aides are used to boost academic performance and new memory-enhancing drugs have already been studied in patients with Alzheimer disease (2008). Implantable neural devices such as the "Artificial Hippocampus" have already shown improved memory capacities in mice (Berger et al. 2011). As this volume illustrates, the potential for such research is vast and extends well beyond the traditional indications for disease treatment and prevention.

Even proponents of neuroenhancement research often raise a cautionary flag about the unregulated and unabated pursuit of these technologies (Greely et al. 2008). Careful research is essential for assessing the risks and benefits of interventions while providing for appropriate regulations and safeguards. Even high-risk or harmful enhancement drugs or technologies might benefit from research that makes their use safer. In this way, neuroenhancement research might produce a more traditional benefit for biomedical health, at least broadly construed (Des Jarlais 2000).

The Problematic Biomedical-Enhancement Distinction

Arguments in favor of enhancement research frequently draw comparisons between enhancement interventions and previously established biomedical interventions. For example, Lev et al. argue that vaccines should be considered as a kind of biomedical enhancement. These interventions boost a normal immune system;

enhancing the body's defenses against harmful pathogens. If vaccines "enhance" a normal immune system, then future research investigating corrective surgery for age-related vision loss or memory enhancement for age-related dementia processes would be similarly permissible (Lev et al. 2010). Each of these interventions improves a normal physiologic process for an otherwise healthy individual without generating much ethical controversy.

Of course, vaccines and corrective vision surgery are closely associated with a biomedical concept of disease and health. While normal physiologic processes are enhanced, they are improved in order to combat highly virulent pathogens or debilitating functional deficits. The objective is not to simply enhance a normal human capacity for its own sake (Daniels 2000). Even interventions designed to improve eyesight or memory in the elderly do so in order to prevent recognized diseases such as presbyopia (farsightedness) and/or dementia. While eyesight and memory certainly decline with age, there are established biomedical criteria for deciding when such age-related processes cross a threshold into "disease" and warrant intervention or additional research. Such criteria may be disputed, but the risk-benefit calculus that drives research in these areas relies on recognized biomedical standards to justify the risks of research and intervention (Juengst et al. 2003).

"Dual use" interventions further complicate the biomedical-enhancement distinction. Many potential neuroenhancement interventions were originally studied and approved for biomedical indications (Lev et al. 2010). Pharmaceuticals like modafinil are approved for narcolepsy and sleep-related disorders, but they show promise for cognitive enhancement for soldiers in combat situations and physicians during overnight call (Normann and Berger 2008).

Modafinil has already gained approval for clinical indications, and if the drug can also be used to improve performance, particularly in stressful and socially important situations, why prohibit investigations of these applications? Clinical research has already established the safety and side-effect profiles of such drugs; additional research would only study efficacy among healthy volunteers. Dual use interventions seem to bridge the conceptual gap between biomedical and enhancement-related research and treatment objectives, particularly when a clear social benefit is present.

Problems of Paradigm

The publication of *The Belmont Report* in 1979 set the ethical standard for human subjects research in the United States. The report made explicit the need for proper informed consent, a thorough assessment of risks and benefits, and fair subject selection in all research involving human subjects (The National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research 1979). These requirements were based on more fundamental ethical principles of respect for persons, beneficence, and justice. The publication of the US Department of Health and Human Services (HHS) policy 45CFR 46 also known as the "Common Rule" codified the Belmont findings into US federal policy, making provisions for

Institutional Review Boards (IRBs) and requirements for consent in biomedical and behavioral research. This policy has even been adopted by several non-health-related federal Departments ranging from the Department of Defense to the Department of Agriculture (U.S. Department of Health and Human Services 2009).

Under this paradigm of biomedical research ethics, several conditions are specific to the ethical practice of biomedical research and presumably neuroenhancement research. Ethical research must (1) have health-related social value, (2) be scientifically valid, (3) use fair subject selection, (4) involve a favorable risk-benefit ratio, (5) be independently reviewed, (6) satisfy informed consent requirements, and (7) respect enrolled participants (Emanuel et al. 2000). Most of these conditions for permissibility are not particularly problematic or controversial for neuroenhancement research projects. There is little dispute about the importance of sound scientific methodology, informed consent, and proper respect of enrolled research participants.

However, requirements for health-related social value and favorable risk-benefit ratio present the most serious challenges to any neuroenhancement research activity (Lev et al. 2010). By definition, neuroenhancement research need not be oriented to disease or ill health. In fact, dual use interventions, such as modafinil, are approved by drug agencies for biomedical indications only; any indication for enhancement is a form of “off-label” use (Bostrom and Sandberg 2009). It is not clear then that the logic of dual use interventions can be applied to drugs or techniques pursued primarily for enhancement purposes; it is even less clear for technologies with no known biomedical indications.

In this way, neuroenhancement technologies cannot claim to possess a medically conceived “health-related social value.” Weighing risks and benefits in such a non-biomedical context requires a fundamentally different calculus. In traditional biomedical research, the additional risks of a research intervention are justified by the harmful effects of disease or ill health. Without direct, primary biomedical applications, neuroenhancement research would seem to lack an appropriate justification for allowing subjects to take on additional risk (Bostrom and Sandberg 2009).

Of course, that is, if one assumes that research should apply strictly to a biomedically conceived notion of health-related social value. The promise of neuroenhancement technology extends well beyond the limits of traditional biomedicine into areas like personality, aging, education, job performance, and athletics, to name a few. A biomedical concept of health relates to such social values only indirectly. The issue then is how to define health and whether a notion of health tied to neuroenhancement requires more than what a biomedical model can offer.

In 1948, the World Health Organization (WHO) defined health as “. . .a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity” (2003). This expansive definition could easily be construed to include neuroenhancement research and interventions. Cognitive and memory enhancements, for example, show obvious potential benefits for mental, social,

and even physical well-being. Such a definition, however, risks conflating health with other goods such as happiness or success (Kass 1975). A biomedical notion of health relies on concepts such as "sickness" and "abnormal" in order to articulate its goals for research and justify its interventions (Bernard 1927). "Well-being" requires neither a similar notion of normal or abnormal, nor a well-described biomedical research standard by which to measure the success or failure of treatment. Such a non-biomedical description of health fails to explain how research might be pursued safely and effectively.

And yet, many potential neuroenhancement drugs and technologies, such as modafinil, have emerged via biomedical research (Turner et al. 2003). Expanding notions of health and a receptive medical profession have enlarged biomedicine's reach into historically nonmedical areas such as behavioral modification, psychology, and cognitive performance. Research dollars and institutional infrastructure have followed. The result is a modern discussion and approach to health that is dominated by biomedicine to the exclusion of other notions of health and sources of well-being (Kass 1975).

We encounter two major problems for neuroenhancement research under an all-encompassing biomedical paradigm. First, we run the risk of pathologizing the normal. These debates have already been played out very publicly in the most recent revision of the Diagnostic and Statistical Manual of Mental Disorders (DSM-V) over controversial diagnoses such as Temper Dysfunctional Disorder with Dysphoria and the Binge Eating Disorder (Cooper 2010). Medicalizing otherwise normal physiologic processes, such as aging or personality, affects more than diagnostic integrity. It disrupts social ties that solidify around care for the elderly (Glannon 2002) and threatens to remove personal responsibility for inappropriate or even illegal behaviors (Kass 2003). Second, we lose the biomedical concept of an "indication" for treatment or research. How much age-related memory loss is abnormal and who decides? It should be made clear that no medical treatment has an indication without a patient's informed consent, but this is not in dispute. Indications in neuroenhancement are set by the individual not biomedicine. There are no broadly accepted concepts of symptoms, signs, diagnosis, disease, and treatment to direct conduct in neuroenhancement research (Juengst et al. 2003).

Toward a Consumer-Based Model of Research Ethics for Neuroenhancement

The limitations of a biomedical research ethics model for neuroenhancement research make clear the need for a new approach. A new model would need to allow for highly subjective notions of risk, benefit, and efficacy within broad constraints of the law. Such a model would also likely require a different notion of informed consent.

In health-related matters, the term "consumer" as opposed to research subject or patient has been controversial. Critics argue that the word "consumer" describes health-related research activities inaccurately as a purely commercial transaction.

The term denies the vulnerability of research participants and the power differential inherent in a physician-patient or researcher-subject relationship (Tallis 1999). The concept has also been controversial and suffers from political associations with unpopular healthcare delivery programs like managed care (Jordan and Court 2010). These critics argue that the resistance to the term "consumer" over time is a strong testament to its danger in health-related encounters.

Proponents of the consumer concept argue that the word "subject" or "patient" is passive and implies a biomedical paternalism of a bygone era. The term "consumer" is even a stronger term than the more recent term "participant" as it reflects the priority of preferences over indications and subjectivity over objectivity. It is also a more complete concept and accounts for the full spectrum of research priorities including non-biomedical areas such as cosmetics, fertility, and lifestyle options (Neuberger 1999).

This debate raises important issues for the ethics of neuroenhancement research. Undeniably, the word consumer has found a place in healthcare today because it serves some function. Enhancement therapies like cosmetic surgery and memory drugs do not conjure up the same notions of vulnerability that justify the use of the word patient, subject, or even participant. Decisions to pursue these interventions are made by healthy individuals with a myriad of goals in mind, health-related or otherwise.

The relationship between a researcher and the research participant or subject is decidedly changed when enhancement is considered. The model for such decision-making is no longer biomedical because the concepts of symptoms, signs, and disease no longer apply. The consumer dictates that indications for the service and the value or "benefit" of the intervention. Research conducted under such a model changes in a number of ways.

First, research priorities are set by consumer demand. Much as any commodity is valued on the basis of consumer demand, the demand for neuroenhancement therapies should drive how research projects are prioritized and funded. Second, benefit must be defined by the consumer and not the researcher or the larger research community. While objective measures exist for assessing performance in, for example, memory or concentration, the value of such measures and our understanding of "efficacy" will be dictated by consumer satisfaction and not by reference to any concept of disease or what is "abnormal." Third, risk must be equitable but not necessarily minimal. Consumer research is subject to lawful restraints, but consumers are allowed more freedom to engage and support research than participants in biomedical research. Hannson and others have argued that the biomedical concept of informed consent is a conceptual failure in the commercial setting due to fundamental differences in the structure of business relationships versus biomedical relationships (Hansson 2006). Fourth, methods in research design must account for consumer feedback. These methods are used in biomedical research, but the difference is the high priority, given such feedback in the enhancement setting. Fifth, researchers have a duty to inform consumers of the latest results and the potential for any harmful effects that may result from the use of neuroenhancement products (National Health and Medical Research Council 2001).

The traditional ethical requirements for biomedical research are helpful to consider but not necessarily required under a consumer model. Requirements such as scientific validity, fair subject selection, independent review, informed consent, and respect for enrolled participants should remain. Under a consumer model, research into neuroenhancement might address a myriad of consumer-driven social values that would not be considered in biomedicine. A favorable risk-benefit ratio takes on new meaning as well. Within constraints of the law, consumers are allowed to take on considerable risk for the sake of many different health and non-health-related benefits. Vulnerable patient populations might still be defined and protected via regulation, but such categories need not incorporate a biomedical definition necessarily.

Potential Hazards and Future Directions

Establishing a consumer model as the basis for neuroenhancement research is not without significant challenges. Ill-defined boundaries between biomedical research and enhancement research will make some neuroenhancement research projects difficult to assess outside of a biomedical regulatory framework. For neuroenhancement research involving human subjects, the role and scope of regulatory oversight committees would be uncertain in many cases. For example, what requirements should exist for informed consent when this concept appears unintelligible in non-biomedical contexts (Hansson 2006)? Finally, who has the authority to determine "appropriate" weighting of risks and benefits when such a calculus is so highly subjective under a consumer-based model?

Professional oversight would also pose a significant hazard for those neuroenhancement technologies requiring professional expertise or approval. Normally, professional conduct falls under several layers of oversight including department heads, professional societies, licensing bodies, institutions, and state and federal governments. Professional activities, research or otherwise, that fall outside of these established authority structures would likely expose research participants to unnecessary and perhaps increased risk.

However, cosmetic surgery might serve as a model for professional neuroenhancement research and practice. Coleman has argued that cosmetic surgery and related research provide a valuable professional service even if indications fall outside of a biomedical model of disease. However, Coleman and others have noted that an attempt by the Dutch government to fund cosmetic surgery as medical care proved unsuccessful due to ambiguities in diagnostic and treatment criteria (Coleman 2006).

Critics have argued that cosmetic surgery, and presumably related research, only reinforces undesirable social norms that ought to be resisted; but these same critics have also fallen short of prohibiting or restricting the activity (Tong and Lindemann 2006). The ethical permissibility of cosmetic surgery and research has remained somewhat unsettled in the literature and without convincing objections, research and practice has continued.

Many concerns about the potential hazards of neuroenhancement research could be answered by turning to commercial examples of regulation. Governmental regulations exist regarding air bags and seat belts in passenger vehicles in the United States based on safety concerns. Bostrom and Sandberg have proposed the idea of "baseline acceptable risk" which would permit the use of neuroenhancement technologies below a publicly established risk level (Bostrom and Sandberg 2009). American federal agencies such as the National Highway Traffic Safety Administration (NHTSA) or the FDA could apply similar regulations to make research and use of neuroenhancement interventions generally safe and effective. Such regulations would help to dispel many concerns raised about coercion, fairness, fraud, and safety in the public use of such technologies (Greely et al. 2008). However, concerns would likely persist regarding the use and distribution of interventions outside of the oversight of traditional biomedical institutional bodies.

Properly regulated, however, there seems to be much gained from a shift to a consumer-based model of clinical research in neuroenhancement, particularly given the recent healthcare economic crisis in the United States. The prioritization of such enhancement research would be driven by consumer demand and corporations, rather than government sources, particularly given the subjective quality of indications for enhancement therapy. This shift in funding sources could avoid debates about utilization of scarce resources for nonmedical ends. If such research yielded medically valuable results, these findings could be used as the basis for initiating a formal medical investigation. This would avoid the costly process of biomedical clinical research approval, and free up regulatory bodies like the IRB from overseeing enhancement research.

It could be argued that much of the high cost associated with medical care in the United States would be unaffected by excluding enhancement-related research. Such research is relatively infrequent, typically not federally funded, and unrelated to the main drivers of high cost in the healthcare system in the United States today. However, making a distinction between biomedical and consumer models may also be useful for clinical practice and healthcare decision-making. As healthcare costs continue to rise in the United States, perhaps, we are asking too much of the disciplines of biomedical research and clinical medicine. Acknowledging the limitations of the biomedical model for improving health allows us to use biomedical research more effectively and places neuroenhancement research in a more coherent conceptual ethical framework.

Conclusion

In this chapter, we argue that an ethics of neuroenhancement research, as defined, requires us to acknowledge the limitations of the biomedical model for research involving human subjects. Much of this discussion turns on the definition of health and what biomedicine can do for such a concept. The goals of neuroenhancement therapy lie outside of a purely biomedical notion of health, although there are some intersections and bidirectional influences. Enhancements might improve memory

or cognition, but they do so absent a biomedical risk-benefit standard or criteria for efficacy. A shift to a consumer-based model of neuroenhancement research ethics would provide a useful framework for evaluation of new interventions. This kind of model acknowledges a more pluralistic notion of health, individual liberty, and human thriving. It also establishes an ethical boundary, subject to modifications, between biomedical and enhancement-related research priorities, which preserves healthcare resources for more strictly medical objectives.

decision-making, or the moral failings of psychopaths. If successful, such research might not only allow philosophers to refine their theories based on scientific facts but also might inform social policy.

While research on morality comes from a range of disciplines, including psychology, economics, and the social sciences, this chapter will focus on the subset of this research that uses the tools of neuroscience (primarily fMRI) and is explicit about testing hypotheses related to moral sentiment, choice, cognition, and action in humans. We will focus our attention here not only because the technology and methods used in this research, and their strengths and weaknesses, are unique but also because this research has proven fascinating to the general public and policy-makers, which substantially broadens the impact that this research may have.

Ultimately, while the marriage of neuroscience and philosophy has tremendous potential to advance our understanding of ourselves as moral beings, we must be careful to limit both our scientific and philosophical conclusions to what the research can reasonably tell us, based on the limits both of the technology and of our ability to integrate centuries of philosophical thought into research design.

Introduction

Over the last 10–15 years, the tools of neuroscience have increasingly been employed to address questions long considered the realm of philosophers, including questions of moral sentiment, choice, cognition, and action. This research seeks to identify the structures within the brain that function in and are the basis of human morality, to improve our understanding, for example, of the role of emotion in moral decision-making, or the moral failings of psychopaths. If successful, such research might not only allow philosophers to refine their theories based on scientific facts but also might inform social policy.

While research on morality comes from a range of disciplines, including psychology, economics, and the social sciences, this chapter will focus on the subset of this research that uses the tools of neuroscience (primarily functional magnetic resonance imaging; fMRI) and is explicit about testing hypotheses related to moral sentiment, choice, cognition, and action in humans. We will focus our attention here not only because the technology and methods used in this research, and their strengths and weaknesses, are unique but also because this research has proven fascinating to the general public and policy-makers, which substantially broadens the impact that this research may have.

This fascination stems both from the technology used (fMRI) and from the questions being asked. The technology allows us to peer into the brain and watch it in action, which is both marvelous and mystifying: marvelous to have such access to the organ that is so closely linked to our identities; mystifying as we try to interpret what we see there.

It is important, however, to recognize the weaknesses of both the technology and of some efforts to solve philosophical puzzles through science. While the marriage of neuroscience and philosophy has tremendous potential to advance our understanding of ourselves as moral beings, we must be careful to limit both our scientific and philosophical conclusions to what the research can reasonably tell us, based on the limits both of the technology and of our ability to integrate centuries of philosophical thought into research design.

Morality

Throughout this chapter, the term "human morality" will be used rather narrowly, to refer to the attempt to live according to some view of what we should do or how we should live and to work out which such view, if any, can be justified and how our own view might be improved. It is not assumed that such views are normally (or ever) fully articulate or coherent, or that most people explicitly consider their views about how to live before deciding what to do. Furthermore, no particular stance is taken regarding how our views about how we should live and our conduct are related. That said, the discussion will be limited to the conduct of persons who are capable of formulating and rationally revising views about how to live and what to do and of trying to live by them.

The capacity for moral action, in this sense, requires a constellation of more specific capacities. A moral agent needs to be able to ask herself how she should live, to formulate answers to that question, and to rationally revise them as necessary. She will need to be able to experience those emotions that her moral views specifically require, for instance, empathy or outrage. She needs to recognize occasions when her moral views apply and to see what they require of her. And she needs the various capacities that make up the ability to regulate her own conduct. Neuroscientific research that illuminates any of these capacities helps us to understand ourselves as moral agents.

The State of the Science

The small but growing neuroscience literature addressing questions of moral sentiment, choice, cognition, and action may be divided into three broad and somewhat overlapping categories: the role of emotion in moral decision-making, neural correlates of other aspects of human morality, and research on the neural correlates of psychopathy. This section will briefly review this research and its findings concerning the neural correlates of moral sentiment, choice, cognition, and action.

The Role of Emotion

"Neuromorality" research was propelled into the spotlight with a study by Greene et al. (2001) investigating the role of emotion in moral decision-making. Much of this work has involved presenting research subjects with moral dilemmas and asking them to make judgments about the appropriate action in each case while undergoing fMRI. Greene's work, in particular, has been motivated by a pair of philosophical thought experiments called the "trolley" and "footbridge" dilemmas. These dilemmas are very similar but with one significant difference. In each scenario, five people are in the path of an oncoming trolley, and there is one way to save them. In the "trolley" case, five people can be saved by diverting the trolley onto another track, where it will run over one person rather than the original five. In the "footbridge" case, five people can be saved only by pushing a large man onto the tracks below, where he will stop the trolley before it reaches the five. In both cases, one person dies and five people are saved, and in both cases, it is our action that causes that one to die. Despite these similarities, most people respond quite differently to these two dilemmas: they think that it is permissible to divert the trolley, but not to push the man onto the track. In an attempt to tease out the apparent conundrum, Greene et al. posed a range of moral and nonmoral questions to their subjects and looked to see what their brains were doing while they made their decisions.

Greene et al. (2001) hypothesized that the difference in how we respond to these moral dilemmas hinges on the degree to which they engage our emotions. As the authors state, thinking about having to lay hands on a fellow human and push him to his death is "more emotionally salient than the thought of hitting a switch that will cause a trolley to produce similar consequences, and it is this emotional response that accounts for people's tendency to treat these cases differently." As such, the group proposed, when people respond to these "personal" moral dilemmas, they will be more likely to engage the emotional centers of the brain than when they respond to "impersonal" moral dilemmas, such as the trolley problem. In fact, they reported that in both of their experiments, parts of the brain implicated in emotion [medial portions of Brodmann's areas (BA) 9 and 10 (medial frontal gyrus), BA 31 (posterior cingulate gyrus), and BA 39 (angular gyrus, bilateral)] were significantly more active when responding to "moral-personal" scenarios than when responding to "moral-impersonal" or nonmoral scenarios.

Based on this work and subsequent investigations (e.g., Greene et al. 2004; Greene 2007a; Koenigs et al. 2007; Valdesolo and DeSteno 2006), Greene and colleagues affirmed a dual-process theory of moral decision-making (Greene 2007a, b). Greene and colleagues' version of the dual-process theory states that in cases like the footbridge dilemma, moral disapproval is driven by a prepotent negative emotional response involving the medial prefrontal cortex. In a parallel process, utilitarian moral reasoning is employed, potentially supported by the dorsolateral prefrontal cortex (DLPFC). In the absence of an overriding emotional response, "utilitarian reasoning prevails" (Greene 2007a). In difficult cases such as

the footbridge dilemma, the two processes (prepotent emotions and utilitarian reasoning) conflict, signaling the anterior cingulate cortex that cognitive control is needed, which is then implemented by the anterior DLPFC (Greene 2007a).

Moll and colleagues conducted a parallel research program looking at the role of emotion. Based on their and others' work (e.g., Ciaramelli et al. 2007; Koenigs et al. 2007; Moll et al. 2001, 2002a, b; Moll and de Oliveira-Souza 2007a, b; Moll and Schulkin 2009), they have concluded that moral judgment invokes brain regions including the frontopolar cortex (FPC, BA10), lateral and medial sectors of the orbitofrontal cortex (OFC, VMPFC, BA11), medial frontal gyrus (BA 10/46 and 9), right anterior temporal cortex (aTC), and the superior temporal sulcus (STS) of the left hemisphere. Further, Moll et al. propose that the association of moral emotions with ordinary social events or interactions may help motivate your response to such events in the future (Moll et al. 2002b).

Moll and colleagues view social sensibility as fundamental to morality and frame their research accordingly (Moll and Schulkin 2009). These researchers interpret the collective literature somewhat differently than Greene and colleagues, suggesting that rather than the dual-process theory in which reason and emotion are in competition, a more parsimonious explanation for the data is that moral sentiments emerge from the integration of cognition, emotion, and other aspects of decision-making. Moll and colleagues propose that the ability to experience "prosocial" moral sentiments, such as compassion and gratitude, is key, that this is facilitated by the VMPFC-FPC (Moll et al. 2005a; Moll and Schulkin 2009), and that such sentiments emerge from the integration of emotional and cognitive mechanisms, rather than from competition between the two (Moll et al. 2005b, 2006; Moll and de Oliveira-Souza 2007b). Further, they contend that while there is functional segregation at play in the brain, it is between prosocial sentiments and socially aversive sentiments (e.g., indignation, shame), which tend to activate different brain regions, rather than between emotion and cognition, as Greene and colleagues suggest (Moll and Schulkin 2009).

Beyond the Role of Emotion

While much neuromorality research has focused on the role of emotion in moral decision-making, there have also been a number of studies looking at specific moral emotions and other aspects of human morality. For example, Moll et al. (2005a) attempted to distinguish the neurological bases of nonmoral ("pure") disgust and moral disgust (defined as indignation) (Moll et al. 2005b). In this study, 14 subjects were observed with fMRI while reading neutral statements, statements designed to evoke pure disgust (e.g., "One night you were walking on a street. You saw a cat eating its own excrement"), and statements designed to evoke indignation (e.g., "As you arrived home, you saw that the nurse had put a spider on the baby's face"). They found that the patterns of brain activation invoked by pure disgust and indignation were highly similar, with only a few relevant differences, including the differential activation of the more anterior sectors of the OFC, left piriform

cortex (BA13, 38, 47), anterior superior frontal gyrus (SFG; BA8, 9), and right anterior inferior temporal gyrus (ITG; BA20, 21) in the experience of indignation versus pure disgust.

Knoch et al. (2006) investigated the underpinnings of reciprocal fairness in the context of the ultimatum game, in which one player offers a portion of her funds to the other player and the second player can accept or reject offers. If the second player accepts, she receives the agreed portion of the total. If the second player rejects, both players receive $0. While this game was being played, Knoch and colleagues disrupted the DLPFC using transcranial magnetic stimulation and found that stimulation/disruption of the right (but not the left) DLPFC lowered the probability that the second player would reject low offers, though she still judged those offers to be unfair. The authors concluded that the right DLPFC supports the implementation of fairness goals when faced with a conflict between fairness and self-interest.

Young and Saxe (2008) looked at the role of “theory of mind” in moral judgment. In order to judge a person’s actions, we must have beliefs about what that person believes she is doing and what she thinks the outcome of her action will be. For example, if a woman puts poison in her colleague’s coffee, reasonably thinking that the substance is sugar rather than poison, we will judge her actions differently than if we believe that she knows that the substance she is putting in her colleague’s coffee is poison. Young and Saxe reported that the process of belief attribution in such cases includes two components: belief encoding (forming a representation of our colleague’s belief about the white substance) and belief integration (using that belief in combination with the outcome to judge the morality of our colleague’s action). Belief encoding, they report, recruits the right temporoparietal junction (RTPJ), the precuneus (BA7), and, to a lesser extent, the left temporoparietal junction (LTPJ). The authors report that these same regions are recruited, though to a different extent, for belief integration, wherein the encoded beliefs are incorporated with other relevant information, such as the outcome of the action in question, enabling moral judgment. However, they conclude that the medial prefrontal cortex is uniquely recruited for processing belief valence (e.g., negative vs. neutral).

More recently, Cushman et al. (2012) examined the difference between people’s reactions to and judgments about harmful actions versus harmful omissions, as a way to get at the broader question of whether moral judgments tend to be intuitive and automatic (the “automaticity hypothesis”) or rather the result of explicit reasoning (the “rule hypothesis”). It has long been recognized that individuals tend to judge more harshly harmful actions than harmful omissions (the “omission effect”). The authors reported that their data support a version of the automaticity hypothesis and fail to support the rule hypothesis, demonstrating that increased cognition (evidenced by differential recruitment of the DLPFC; BA9, 10) was required not when individuals conformed to the omission effect but when they failed to demonstrate this bias. Put another way, Cushman et al. suggest that the omission effect is the result of automatic processes, but that these processes can be overcome with explicit cognitive effort.

Psychopathy

One distinct area of neuromorality research focuses on the differences between psychopathic and non-psychopathic individuals (Blair 2007; Glenn et al. 2009; Gregory 2012; Harenski et al. 2010; Raine and Yang 2006; Weber et al. 2008). There are two primary explanatory theories for psychopathy: the "somatic marker hypothesis" (Damasio 1994) and the "violence inhibition mechanism" model (Blair 1995). The somatic marker hypothesis holds that an inability to associate physiologic responses ("somatic markers"), such as increased heart rate, and related emotions, such as fear or anxiety, with stimuli (e.g., seeing a snake in your path) impairs the individual's ability to make efficient and appropriate decisions based on past experience. Such somatic markers can help us or bias us to choose one action over another based on how it made us feel the last time we faced a similar choice. The loss of this ability is associated with damage to the vmPFC and the resulting poor decision-making and antisocial behavior. The violence inhibition mechanism model holds that humans, like other social animals, have an innate response to "submissive" or "distress" cues from others, such as a look of fear or pain on someone's face, and that these cues prevent us from committing violence against those who are not aggressors. The loss of the violence inhibition mechanism leads to a lack of empathy and the development of psychopathy.

Several research teams have reported and discussed compromised function in the vmPFC and the amygdala (Blair 2007; Glenn et al. 2009; Harenski et al. 2010; Raine and Yang 2006). Other areas that have been implicated in psychopathy include the temporal cortices and posterior cingulate (e.g., Harenski et al. 2010; Raine and Yang 2006). This dysfunction, it is claimed, results in an inability to learn to associate particular actions with others' distress and to be aversive to those actions as a result.

Scientific Issues

As Poldrack has written (Poldrack 2006, 2007, 2011), there is still much that we do not understand about what fMRI can and cannot tell us. Poldrack and others have warned in particular of the related challenges of region of interest (ROI) analyses and reverse inference with fMRI data. ROI analyses, which focus preferentially on the results from specific regions of the brain following collection of data from the whole brain, are done for several reasons, including simply making the task more manageable by exploring the results for particular regions of the brain one at a time in data collected in a detailed whole-brain analysis, statistical analysis to reduce the degree of correction necessary for multiple testing by narrowing the amount of data being analyzed, and examining the activity of "functionally coherent" regions of the brain in response to a manipulation (Poldrack 2007). The last of these, the use of ROI analysis to assess the response of a particular brain region to an experimental manipulation, can be particularly

challenging due to the difficulty of attributing a single function of interest to a particular brain region (such "reverse inference" is discussed further below). This is compounded by the difficulty of defining ROIs themselves – not only is it a subjective process generally, but an ROI will be slightly different for each research participant due to structural and functional variability across human brains (Poldrack 2007). As such, multiple subjective judgments are being made in any given experiment, including about the threshold for calling a difference in regional activation between the case and control conditions, determining the size of the region of interest, and placing the demarcating line around the region of interest. For this reason, researchers must be circumspect in the conclusions drawn on the basis of the results.

Reverse inference in fMRI studies is the fairly common process of inferring the presence of particular mental states based on brain activation patterns in response to a manipulation. This process has been criticized for reasons including the lack of adequate background information (e.g., base rates of activation in particular brain regions), the lack of specificity of many brain regions, and the lack of clear or consistent ways of talking about the functions of different brain regions (Poldrack 2006, 2011). The lack of adequate background information, due in part to both the small sample sizes used in most fMRI studies and the historical lack of adequate mechanisms and incentives to share research scans with other researchers, combines with the inherently relative nature of fMRI measurements to make it difficult, if not impossible, to estimate base rates of activation for a ROI (however that has been defined in any given study), though this may be improving (Poldrack et al. 2011). Without knowing the base rate of activation, it is difficult to appreciate the strength of a reverse inference. Further, even if one does know the base rate of activation, if a ROI is activated in response to multiple stimuli (i.e., it lacks specificity), determining which mental state is present is difficult. Finally, even the different mental states that may be present can be difficult to define, since there is no standard way of talking about or describing them (Poldrack 2006, 2011). For all of those reasons, ascribing causation where a mere association is present should be done only with caution, and causal claims that are made should be described as tentative.

One of the reasons reverse inference can lead to inappropriate conclusions is that any given brain region may have multiple functions (Poldrack 2006). For example, in recent reports, the precuneus, which was found, as discussed above, to be involved in belief encoding (Young and Saxe 2008), has also been described as: "involved in determining the precise location of relevant stimuli from various sensory modalities as well as in the subject's preparation to act on it" (Zündorf et al. 2013); "a brain region known to be implicated in visuospatial imagery and more specifically, in shifting attention between targets" (Fonville et al. 2013); "implicated in higher-order cognitive functions, and might therefore contribute in accounting for the abnormal processing of [deontological guilt] stimuli in OCD patients" (Basile et al. 2013); "more involved in processing Chinese characters as compared with English words, more involved in Chinese adults than Chinese children during character reading, and more involved in Chinese

[as a second language] learners with a higher performance" (Cao et al. 2013); and "activations during task switching have been proposed to reflect attentional demands when updating stimulus–response associations" (Barber and Carter 2005). Thus, mere activation difference between a case and control state does not allow the researcher to draw a straight line between a particular mental state invoked by the research manipulation and, in this case, the precuneus.

While lesioning and other behavioral data can strengthen the case for a relationship between a brain area and a capacity, this is also not infallible. In the event of brain injury, other areas of the brain can take over a function previously supported by an injured area, thus compensating for the loss; for example, following a stroke which damages the part of the brain normally associated with spoken language, other parts of the brain can be recruited to support this function, allowing the patient to regain her ability to speak (e.g., Ohyama et al. 1996; Thiel et al. 2006). Given the known plasticity of the brain, as well as related structural and functional variability across individuals, even associations with lesioning or behavioral support should be considered carefully before the associations are claimed as evidence of causation.

Given how little we know, and related to the concerns raised above, there is also a worry about the degree to which the methods we use and the assumptions we make shape and constrain what we will find. This is of particular concern given the small numbers (often ten or fewer) of subjects in many of the studies published thus far investigating neural correlates of moral sentiment, choice, cognition, and action. In addition, these subjects are often university students (age 18–24 years) – a small and particular subset of the population who are unlikely either to be representative of the population as a whole or to capture humanity's diversity in brain structure and function and other relevant factors (e.g., Young and Saxe 2011). What if the results describe only how students at elite universities think about moral dilemmas?

Finally, there is the difficulty of the subject matter itself: moral sentiment, choice, cognition, and action. How one feels about or considers a particular moral dilemma may be colored by one's lived experience. What if contrived moral dilemmas like the "trolley" and "footbridge" scenarios, dilemmas unrelated to the lives of these students, recruit different neural regions or networks than the mundane moral problems of their lives (e.g., Should I cheat on this test?)? Could these actually be studies of moral imagination? To some degree this is unavoidable, as it would be unethical to put subjects in actual moral dilemmas, but again, this should caution against too strong conclusions. As noted by Moll and de Oliveira-Souza (2007b) in discussing the results of a particular study, "That VMPFC patients make more prosocial choices (from a utilitarian perspective) is a reminder of the gulf that divides observable behaviors and internal motivations." To better understand such complex questions of human morality, further research on the basic capacities underlying moral sentiment, choice, cognition, and action – such as decision-making and acting on one's decisions – will be required. Such understanding is necessary for developing testable hypotheses about how these capacities and the mechanisms that enable them might be involved in moral sentiment, choice, cognition, and action.

Philosophical Issues

Neuroscientists who study morality are concerned with questions about how we actually make moral decisions. Moral philosophers, on the other hand, are concerned with what we ought to do: with which decisions are the right ones, which kinds of lives we ought to lead, and which goals we ought to pursue. These are quite different questions, and while answers to the first set of questions are surely relevant to the second, they are not themselves answers to them, nor do they imply such answers in any obvious way. In this section we will consider some ways in which neuroscientific research about morality might be thought to bear on ethics.

Settling Questions About the Basis of Morality

Some neuroscientists have taken their work to bear directly on fundamental issues in moral philosophy. Thus, Marc Hauser writes: "Neuroimaging is at its best and most useful when there are competing psychological theories, with one side proposing a unitary mechanism and the other proposing multiple mechanisms. If you are a Kantian creature, you think that the key process underlying moral judgment is deliberate reasoning based on clearly articulated principles. Consequently, the areas involved in such reasoning, be they specific to morality or not, should not only turn on but have the most active voice. If you are a Humean creature, you think that only our emotions play a role in moral judgments, and, thus, the circuitry underlying the production and perception of emotions should turn on. There are, of course, many other possibilities . . ." (Hauser 2006, p. 220).

In this passage and elsewhere, Hauser confuses two sets of questions. The first set, which neuroimaging can illuminate, is: what brain structures are activated when we make moral choices in everyday life? Specifically, what roles do reason and emotion play in these moral choices? The second set, on which the bearing of neuroscience is much less clear, is: How might we justify moral claims and what role might reason and emotion play in that justification? These two sets of questions are quite different, and answers to one do not necessarily translate into answers to the other.

The moral philosophers Hauser mentions are not describing the ways in which we make moral decisions in everyday life but the basis on which moral claims can be justified. Hume believes that we cannot justify any moral claims on the basis of reason alone; Kant believes that we can. Neither view directly implies anything about how we make moral judgments in everyday life.

Morality as Rationalization of Choices Made on Other Grounds

It has been suggested (Funk and Gazzaniga 2009; Haidt 2001) that moral reasoning is simply a post hoc rationalization for decisions made on nonrational grounds. If this were true, then the questions that interest moral philosophers would have no

practical point: if our views on moral questions could not affect our conduct, then our interest in answering those questions correctly would be purely academic. It would not be surprising to discover that people sometimes believe that they have acted on a moral principle when in fact their actions had a different cause. People are sometimes mistaken and they sometimes confabulate, as Funk and Gazzaniga note.

However, it would be quite surprising to discover that we never ask ourselves what to do, try to reason our way to an answer, and then act on it. It is worth noting both how difficult it would be to provide evidence for this claim, which purports to hold for all moral reasoning, and how implausible it is, since the fact that we sometimes do ask what we should do and then act on our answer seems clear from experience. Moreover, it is not clear that moral reasoning could always be confabulation, since we sometimes engage in moral reasoning before making a decision, rather than producing it as a rationalization after the fact.

In fact, Haidt does not deny that we sometimes reason our way to a decision and then act on it. He just thinks that we do so only "rarely" (Haidt 2001, p. 189). Haidt presents this view as a hypothesis in need of further testing, and his arguments for it are directed not against the view that our moral views can influence what we do but against the view that virtually nothing other than reason governs moral action, a view that his opponents need not accept. Similarly, Funk and Gazzaniga "suggest" that "rather than a causal determinant in the moral decision-making process, moral reasoning is most usefully thought of as an attempt to explain the cause and effect of our moral intuitions that draws upon all available explicit information about a given situation" (2009, p. 680). While they do provide evidence that reasoning is sometimes post hoc rationalization or confabulation rather than a cause of our action, they do not provide evidence that this is always true. Moreover, the evidence they do provide is suggestive rather than conclusive.

Greene's Dual-Process Theory

As noted earlier, Greene proposes a dual-process theory of moral reasoning. For evolutionary reasons, he argues, we are normally reluctant to hurt other people. In "personal" moral dilemmas in which we must decide whether or not to hurt another person, our moral judgments tend to be driven by these emotional responses. But in "impersonal" cases in which the harm we impose on others is less obvious, those emotions do not come into play, and we can rely instead on a rational assessment of the costs and benefits of our alternatives.

Greene argues (Greene 2007b) that this view provides evidence that deontological moral theories are rationally unfounded. "There is a remarkable correspondence between what rationalist deontological theories tell us to do and what our emotions tell us to do" (Greene 2007b, p. 68). What explains this correspondence, Greene argues, is not that our emotions track an independent and rationally

discoverable moral truth but that many of our moral beliefs, and in particular those that we draw on in formulating deontological views, are essentially rationalizations of our emotional responses.

One might question this argument on a number of grounds. Greene sometimes seems too quick to draw general lessons from the contrast between the "trolley" and "footbridge" cases. In those cases, unwillingness to directly hurt others lines up with deontology, and setting our emotional responses aside lines up with consequentialism. But this is not always true: when we need to choose between lying and telling a truth that will both hurt someone directly and produce bad consequences overall, it is consequentialism that lines up with our emotional responses, and deontology that requires that we set those emotional responses to one side on the basis of rational reflection.

Similarly, Greene's claim that there is a "remarkable correspondence" between the views of rationalist deontologists and our instinctive aversion to harming others relies in part on his choice of examples. There are cases, some of which Greene cites, in which our moral intuitions fit deontological moral theory. But there are other cases in which they do not. Kant believed that it is wrong to lie to a would-be murderer who asks where he can find an innocent person whom he wants to kill, and that we should do what is right regardless of the consequences. Neither claim accords with most people's moral intuitions.

The most important problem with Greene's argument, however, is that it begs the question against the rationalist deontologist. Rationalist deontologists believe that we can justify some set of non-consequentialist moral rules on the basis of moral reasoning. If they can provide such a justification – a valid argument for the truth of those moral rules – then that argument would explain why they accepted those rules, and any correspondence between those rules and our emotional responses to hurting other people would be coincidental. If there is no such justification, then rationalist deontology is false, whatever its relation to our instinctive emotional responses.

Greene's dual-process view of moral reasoning does provide a possible explanation for some of our non-consequentialist moral judgments. In so doing it helps us to understand how our moral lives might be as they are even if we have no rational justification for some of our moral beliefs. But his theory does not imply that there is no such justification.

What Neuroscience Can Do

Morality is concerned with questions about how should we live. Neuroscience does not aim to answer these questions. For this reason, neuroscientific results are unlikely to directly imply the truth or falsity of any general moral view. However, precisely because neuroscience tells us about the brain structures that underlie our ordinary moral decisions, our attempts at self-governance, and our conduct, they are relevant to moral philosophy in a different way.

Morality is by its nature practical. We try to figure out how we ought to live not only because this question is interesting but because we want to put our answers into practice. The more we understand the mechanisms that underlie our conduct, the more clearly we can see how these mechanisms might go wrong and how to make it as likely as possible that they function as we would wish them to.

For instance, Greene and Paxton (2009) attempted to determine whether subjects who did not take advantage of opportunities for dishonest gain acted as they did because they resisted temptation or because they did not find those opportunities tempting in the first place. Greene and Paxton argued that if subjects behaved honestly because they were able to resist temptation, then they ought to display increased activity in brain regions associated with self-regulation and control, whereas if they behaved honestly because they were not tempted by the prospect of dishonest gain, such activity would not be required. They reported that subjects who behaved honestly displayed no additional activity in regions associated with self-control and therefore concluded that those subjects generally were not tempted by dishonest gain. Moreover, they found that subjects who behaved dishonestly did display increased activity in those regions, and that this was true even on those occasions when those subjects acted honestly.

Greene and Paxton's results do not imply that people who want to be honest have no reason to try to develop willpower. After all, if one finds oneself tempted by dishonest gains, then it is too late to try to make oneself into the sort of person who would not be so tempted. But they do imply that if we can manage to avoid being tempted by dishonesty, either by cultivating better habits, avoiding occasions for dishonesty, reframing the issues, or by some other means, then we would be well advised to do so. Moreover, their results imply that it is more important to try to avoid being tempted in the first place than to develop willpower. Had Greene and Paxton found the opposite – that temptation affects everyone equally, but only some are able to resist it – then the opposite would be true.

These results do not themselves settle any major debates in moral philosophy. Arguably, no plausible results in neuroscience could settle those debates. Instead, they help us to understand what is involved in actually trying to live a moral life and in so doing illuminate the terrain moral agents must navigate, the obstacles they are likely to confront, and the tools their brains provide to help them on the way.

Research Ethics

There is a great deal we can learn from the brain with current technology, but scientific integrity demands honesty and modesty in the face of many unknowns. Investigators must be careful to pose research questions that can be rigorously addressed given the current state of the technology, the outcomes we can reliably measure, and our ability to analyze and understand the resulting data. Investigators must also be appropriately circumspect in drawing conclusions from this work. As the field develops, perhaps more will be able to be said about the relationship of events in the brain to the capacity to make moral decisions, but currently, justifiable

claims based on this research are fairly modest. Caution may be particularly important in this field given the strong public interest in questions of moral sentiments and the brain. Further, the answers to such questions may have direct implications for our understanding of moral responsibility and ultimately criminal responsibility, which also suggests caution against making too-broad claims based on current research.

Beyond these issues of scientific integrity, so long as the science is focused on imaging studies, there are few other unique research ethics issues raised, except perhaps in the case of psychopaths who may be incarcerated or otherwise unable to give fully informed and voluntary consent. If or when the field begins to venture into research on enhancing (or diminishing) the morality of research subjects, the ethical landscape will surely change.

Conclusion and Future Directions

While neuromorality research is interesting, has great promise to inform many questions related to the neural correlates of moral sentiment, choice, cognition and action, and has undeniably captured the imagination of the public, this is a young and in many ways primitive field. Both neuromorality researchers and the public must appreciate and acknowledge the difference between determining the neural correlates of moral sentiment, choice, cognition, and action in any particular case and resolving the difficult philosophical questions of what is or how to lead a moral life. Going forward, additional collaboration between philosophers and neuroscientists is critical to improving the chances that the research has the desired effect of informing (though not solving) debates in moral philosophy and at the same time that researchers do not overstate the philosophical implications of their conclusions.

Contents

Abstract

This chapter is an introduction to the section on neuroenhancement, which is regarded as an intervention in the central nervous system in order to "improve" certain aspects of a person's "healthy" or "normal" performance. This can be accomplished by pharmaceutical means, surgery, and/or technology. The section on neuroenhancement begins with a chapter looking at pharmaceutical mood enhancement. It then centers on smart drugs followed by a chapter on the use of brain-computer interfaces for enhancement purposes and another one analyzing moral neuroenhancement. The section concludes with a chapter presenting some general reflections on neuroenhancement.

Introduction

Since the dawn of history, people have aimed at self-improvement. They have attempted to develop their traits and faculties in a variety of ways depending on the specific set of cultural ideals *en vogue* at the time. Gilgamesh searched for immortality. The Homeric heroes strived for excellence in fights and wars. The Olympic

athletes pushed the boundaries in sports. Early Christian hermits aspired after spirituality and holiness. Medieval manuscript illuminators arduously developed their artistic skills. Currently, the "self-improvement industry" is huge.

For a long time, medicine did not play any role of significance in this widespread human attempt at self-improvement. Hippocratic medicine was focused on trying to make sick people healthy again. It conceptualized health as equilibrium between four humors: blood, phlegm, black, and yellow bile. An imbalance of these humors caused disease. Therefore, Hippocratic medicine was led by the normative ideal of *restitutio ad integrum*: restoration of the original balance. The Hippocratic conceptualization of health and disease, and the normative framework associated with it, dominated medicine for more than two thousand years.

In addition to these Hippocratic notions of curing diseases and restoring health, ideas of using medicine in order to improve people beyond what could be regarded as healthy or normal were first tentatively addressed by Francis Bacon in his *New Atlantis* (1627) and Rene Descartes in his *Discours de la méthode pour bien conduire sa raison et chercher la vérité dans les sciences* (1637). Both philosophers focused on an imagined and desired future state of medicine. They both argued that medicine would have a huge potential for future development, if only it employed the right scientific methodology. A century and a half later, these early ideas were even more explicitly heralded by Marquis de Condorcet in *Esquisse d'un tableau historique des progrès de l'esprit humain* (1795), where he discussed the extension of the maximum lifespan and the limitless perfectibility of man.[1] These seventeenth and eighteenth century enthusiastic ideas about medicine had increasingly moved away from the traditional Hippocratic normative framework. However, focused as they were on an anticipated future state of medical science, they were somewhat remote from medical practice at the coalface.[2]

Arguably, the state of medicine imagined in the writings of Bacon, Descartes, and Condorcet has now at least partially been realized. It is true, we are still neither able to eradicate all pain and suffering, nor to extend the maximum human life span. Nevertheless, medical enhancement is a growth industry. A large part of this industry is currently focused on the improvement of looks. Modern medicine and dentistry have advanced countless new approaches to meet this goal: botox, breast implants, laser hair removal, liposuction, face lifts, tooth reshaping, veneers, and tooth bleaching. Another important chunk is to do with the improvement of performance in sports and the military.

Besides aesthetics, athletic endurance, and military performance, expectations are currently also directed to the medical improvement of various aspects of our mental live. To this effect, two approaches have dominated the academic debate in the last few decades. First, the focus was on genetic interventions. A theoretical advantage of genetic enhancement was that improvements in the germ line would

[1]See Gordijn 2006 for further analysis of this early philosophical literature on the future prospects of medical science.

[2]See Wiesing 2008 for further analysis of the history of medical enhancement.

be inherited by future generations. As a result, improvements would not have to start from scratch in each new generation. Of course, this advantage would directly turn into a disadvantage in case disproportionate harms are passed on to future generations as a result of unsuccessful germ-line interventions. Be that as it may, the discussion around projections centered on germ-line enhancement were somewhat dampened when, in the course of the 1990s, clinical trials demonstrated that even "simple" somatic gene therapy turned out to be much more problematic than imagined in advance. The problems surrounding genetic interventions may have created more room for excited projections centered on neuroenhancement: medical interventions more directly targeting a healthy central nervous system in order to improve its functions. This shift has triggered a new debate on the prospects and the ethics of neuroenhancement.

In Google Scholar, publications with the word "neuroenhancement," in the title turned up for the first time in 2004 (search performed on 31 March 2013). As is to be expected, the term "neuroenhancement" is differently defined by different authors. For example, neuroenhancement is sometimes narrowed down to "the use of pharmaceuticals to enhance cognitive function in cognitively normal people" (Boot et al. 2012, p. 181; cf. Eickenhorst et al. 2012; Normann and Berger 2008; Partridge et al. 2011). Others use a broader concept of neuroenhancement with a more inclusive range of methods as well as additional mental functions as potential targets of improvement. An example of such a broader definition of neuroenhancement is the "improvement in the cognitive, emotional and motivational functions of healthy individuals through, inter alia, the use of drugs (Repantis et al. 2010, p. 187).

In this section, neuroenhancement is loosely defined in a broad sense as an intervention in the central nervous system, by using pharmaceutical means, surgery, and/or technology (brain-computer interfaces or other neurotechnologies), in order to "improve" certain aspects of its "healthy" or "normal" performance. Of course, there are meticulous debates about what exactly constitutes "health," what level of performance can be regarded as "normal," and what kind of change may be conceived of as "improvement." However, this section does not primarily focus on these basic philosophical questions, even if they cannot be avoided altogether. Instead, it first and foremost discusses a few important types of neuroenhancement and a selection of ethical questions that they raise, without attempting to present an exhaustive overview.

Section Overview

The neuroenhancement section starts with a chapter on ethical issues of pharmacological mood enhancement by Maartje Schermer. First, Schermer discusses the concept of mood enhancement. This concept turns out to be quite difficult to demarcate. In addition, she gives an historical overview of the ethical debate about mood enhancement. The early mood enhancement discussions start with the publication of Peter Kramer's book *Listening to Prozac* (1993) and center on

Selective Serotonine Reuptake Inhibitors (SSRIs), a set of drugs – Prozac being a well-known example – originally developed in the 1970s to tackle depression. These drugs were seemingly without any serious side effects and became hugely popular as mood enhancers. However, in the early 2000s, critical questions around the occurrence of side effects and the lack of efficacy surfaced. As a result, the popularity of SSRIs waned during the 2000s, shifting the debate from pharmacological mood enhancement to other kinds of neuroenhancement. However, Schermer believes it is very well possible that emerging neuromodulation technologies might rekindle the debate about mood enhancement. In her analysis of the ethical and broader philosophical issues triggered by the prospect of mood enhancement, she covers issues such as the real meaning of happiness, the significance of feelings of alienation, authenticity and its relation to self-discovery and self-creation, the use of psychotherapy versus pharmaceuticals in order to alter mood or character traits, as well as issues of medicalization, disease mongering, and the goals of medicine.

In the next chapter, Alena Buyx focuses on the ethical debate about smart drugs, which is quite intensive at present both in the scholarly and the public arena. Seeking to avoid that her review becomes too speculative, she first surveys the empirical evidence on smart drugs, looking in particular at data about the frequency of their use as well as their effectiveness. In order to delimit her review, she especially focuses on modafinil, methylphenidate, and amphetamines. These drugs have originally been developed for therapeutic purposes. However, they are now also being used off-label for the improvement of cognitive functions by people showing none of the clinical defects that these drugs were originally intended to address. In her review of the ethical debate, Buyx first zeros in on conceptual issues such as the distinction between therapy and enhancement, and what is natural and unnatural. Next, she discusses ethical issues on an individual level such as considerations around safety, efficacy, autonomy, and authenticity. Finally, Buyx analyzes ethical issues triggered by smart drug that might surface on a societal level, for example, increasing inequality and other detrimental societal effects like medicalization and disengagement.

Fiachra O'Brolcháin and Bert Gordijn discuss the use of brain-computer interfaces (BCIs) for enhancement purposes. BCIs pick up brain signals and translate them into commands directing an external gadget. Like the smart drugs and mood enhancers discussed above, BCIs have originally been developed for therapeutic purposes in order to enable patients with brutal physical impairments to control a computer and other devices "by the power of their thoughts." However, they are now increasingly being used for enhancement purposes, for example, for gaming or neurofeedback in sports and the arts. The shift from use for therapeutic to enhancement applications means that the target group of users, formerly exclusively severely injured patients, might slowly but surely become very big, potentially turning BCIs into a phenomenon with considerable societal effects. The chapter anticipates a potential future scenario of widespread BCI use for the purpose of enhancement. After a brief sketch of a variety of ethical issues, the discussion centers on concerns around privacy and autonomy. Further ethical debate is

imperative in order to facilitate regulation that steers the development and use of BCI technologies in desirable directions, reaping the opportunities and effectively tackling the challenges.

Next Thomas Douglas discusses moral neuroenhancement. In contrast to moral enhancement, which has a broad set of approaches at its disposal in order to increase morality, the narrower concept of moral neuroenhancement covers exclusively direct interventions in the brain and its operations, for example, by means of drugs or neuromodulation technologies. Douglas' chapter covers two kinds of moral neuroenhancement that have prevailed in recent scholarly debates, i.e., neuroenhancement of the moral status of individuals and of the moral desirability of their character, motivation, and behavior. Douglas mainly focuses on ethical issues around moral neuroenhancement only turning to questions of feasibility when relevant for the ethical debate. In doing so, he presents a detailed overview of the main lines of argument in this burgeoning academic debate on the ethics of moral neuroenhancement.

Walter Glannon concludes the neuroenhancement section with some general reflections on the topic. He focuses on cognitive and moral neuroenhancement, intentionally leaving out mood enhancement. This focus is due to the fact that – as already mentioned above – in the last couple of years, empirical studies have advanced somewhat disappointing results about the efficacy of mood enhancers when used by healthy people. Glannon is especially interested in assessing the argument stating neuroenhancement is wrong because it negatively modifies human nature. Glannon also discusses the risks and benefits of cognitive neuroenhancement concluding that long-term empirical studies are required to gain more precise knowledge about its benefit-risk ratio. In addition, he examines some of the potential societal effects of cognitive neuroenhancement, such as increased inequality and social coercion to use cognitive neuroenhancers. Finally, Glannon analyzes questions around empirical evidence of the effectiveness of moral neuroenhancement to improve moral sensitivity as well as issues concerning individuals' freedom not to enhance their own moral traits – which may under certain circumstances conflict with community interests if, for example, moral neuroenhancement turns out to be cheap, effective, and without side effects.

Conclusion

The chapters in this section demonstrate that there is a burgeoning academic debate about neuroenhancement. While this debate is intellectually interesting in its own right, it remains to be seen whether the future prospects of neuroenhancement, that inform the contemporary discussion, will materialize as currently imagined. Analogous to the bubbles and busts that seem to dominate economic cycles, ethical debates about emerging technologies do sometimes appear to be characterized by an early focus on somewhat grandiose prospects that are later debunked on the basis of increased empirical data. The debate about mood enhancement seems to be a good case in point.

So at this early stage in the development of neuroenhancement technologies, it is still unclear whether effective and safe ways of neuroenhancement will attain widespread application any time soon – or ever for that matter. And yet precisely because it is impossible to predict the future, it is prudent to be prepared for all eventualities. Of course, ethical discussions should be founded on the results of empirical research. But in order to anticipate upcoming developments, future scenarios have to be analyzed as well. In doing so, it can sometimes admittedly be difficult to avoid a focus on speculative prospects, if only because it is so much more interesting to analyze the ethics of a future scenario significantly different to our current condition than it is to scrutinize the ethical aspects of imminent incremental change. However, as long as the academic debate keenly adjusts its findings on the basis of newly available empirical information about emerging versions of neuroenhancement technologies, their traits, and the various effects of their employment, this should not be an insurmountable problem.

Ethics of Pharmacological Mood Enhancement

76

Maartje Schermer

Contents

Abstract

Pharmacological mood enhancement – the improvement of mood and related mental functions by means of pharmaceuticals – raises a number of philosophical, ethical, and social questions. These questions are partly in line with questions known from the broader debate on human enhancement and partly relate to the ways in which neuroscience and neurotechnologies are affecting our ideas about who we are and how we should understand ourselves. This contribution gives an overview of the mood-enhancement discussion as it has played out in the academic literature over the last 20 years.

J. Clausen, N. Levy (eds.), *Handbook of Neuroethics*,
DOI 10.1007/978-94-007-4707-4_90,

After a brief historical overview of mood enhancement and the associated ethical debate, the most important ethical and philosophical issues regarding mood enhancement are addressed in more detail. These include, first, the nature and value of happiness and human well-being. Secondly, issues regarding authenticity, identity, and the proper view of and attitude towards the self are discussed. Finally, there are questions about the proper role of medicine and the critique on the medicalization of psychological states and traits and the role of industry.

It is concluded that with the advent of new technologies and the increasing importance of optimal mental functioning in modern societies, these issues will remain important in the near future, even if they may no longer be grouped together under the heading of "mood enhancement."

Introduction

Pharmacological mood enhancement – the improvement of mood and related mental functions by means of pharmaceuticals – raises a number of philosophical, ethical, and social questions that have been discussed in both popular and academic literature over the past decades. On the one hand, these discussions fit into the more general human enhancement debate; on the other hand they also relate to the ways in which neuroscience and neurotechnologies are affecting our ideas about who we are and how we should understand ourselves. This contribution will give an overview of the discussion as it has played out in the academic bioethical and neuroethical literature over the last 20 years. It will present the main questions and concerns that have been raised and the different points of view taken on these issues and show how these are related to philosophical and ethical debates and positions on, for example, personal identity, human agency, the goals of medicine, or human well-being.

First, the concept of mood enhancement will be discussed, as well as a number of techniques that may be used for mood-enhancement purposes. Next, a brief historical overview of mood enhancement and the ethical debate on mood enhancement will be given. After that the most important ethical and philosophical issues regarding mood enhancement as they have come up in the mood-enhancement debate will be addressed in more detail. These can roughly be clustered in three groups: first, questions concerning the nature of happiness and well-being; second, questions concerning the effects of mood enhancement on the authenticity, personal identity, or self-image of the person using it; and third, social questions concerning the goals of medicine, the role of industry, and the medicalization of unhappiness.

What Does "Mood Enhancement" Mean?

Mood enhancement is a very slippery concept and is actually not used as such by many of the authors who have participated in the discussion. A first reason why

"mood enhancement" is difficult to define is due to the fact that it is not clear how "enhancement" should be defined. This has already raised significant debate in the literature. Some definitions clearly distinguish between treatment or therapy on the one hand and enhancement on the other. The definition by Juengst, for example, states that "enhancements are interventions designed to improve human form or functioning beyond what it takes to restore and sustain good health" (Juengst 1998, p. 29). A problem with this type of definition is that it depends on concepts of health and disease that are contested themselves; it presupposes a clear distinction between sickness and health that is difficult to maintain, especially in the field of psychiatry and psychology.

The so-called welfarist definition of enhancement does not face such problems, as it states that an enhancement is "any change in the biology or psychology of a person which increases the chance of leading a good life in the relevant set of circumstances" (Savulescu et al. 2011, p. 7). This includes both medical treatment and enhancement of human traits or functioning above "normal" levels, thus including both the treatment of depression or anxiety disorders and making people feel "better than well."

Finally, some definitions also stress the technological or biomedical means of enhancement interventions: "a biomedical enhancement is a deliberate intervention, applying biomedical science, which aims to improve an existing capacity that most or all human beings typically have [. . .] by acting on the body or the brain" (Buchanan 2011, p. 23). Non-technological means for mood enhancement, like cognitive therapy, physical exercise, or good company, are thereby excluded from the ethical debate.

A second reason why it is difficult to define what is meant by "mood enhancement" is that what is often discussed under that heading is not always clearly the improvement of *mood*. Remarkably, in the debate over the ethics of mood enhancement, little has been written about what "mood" exactly is, perhaps with the exception of a phenomenological analysis of mood by Svenaeus (2007). "Mood" tends to be equated with "feeling good" or "being happy," but it is sometimes also taken to refer to a wider variety of emotional states or emotional responses. Moreover, much of the debate is not about mood in a strict sense but about the enhancement of certain desirable character traits such as being spontaneous, outgoing, self-confident, and not shy. Since the 2003 report by President Bush's Council on Bioethics, *Beyond Therapy*, the use of pharmaceuticals to "erase bad memories" – as the use of beta-blockers for the treatment of post-traumatic stress disorder PTSS is called in that report – is also often classified as a case of mood enhancement.

A final specification is that mood enhancement mainly refers to specific means of mood enhancement. In a sense, mood enhancement is nothing new because humans have always used herbal mixtures, drugs, or alcohol to enhance mood. What is new and has sparked the debate is that since the development of pharmacological antidepressants, there are *medical technologies* that can enhance mood and allegedly alter character traits. On the one hand, these medicines appear to be more acceptable to the public than many illicit mood enhancing drugs (like cocaine

or ecstasy), perhaps due to the fact they are considered to be safer and have fewer side effects than such drugs. On the other hand, the use of pharmaceuticals for the improvement of the mood and character traits in more-or-less healthy people raises both popular and academic concerns about the proper limits of medicine and about the ethics of using pharmaceutical means to alter oneself. It is nevertheless remarkable that the debate on mood enhancement has focused exclusively on pharmaceuticals and that the use of mood enhancing drugs or substances like alcohol has never been part of the discussion.

A Brief History of the Debate on Mood Enhancement

Ever since the development of psychopharmacology, there have been ethical concerns and social discussions about the use of pharmaceuticals to help people cope with stress, boredom, and anxieties. Well-known examples include the tranquilizer Miltown in the 1950s or “mother’s little helper” Valium in the 1970s (Elliott and Chambers 2004).

In the mood-enhancement debate as it has developed in bioethics and neuroethics since the 1990s, it was the new wonder drug Prozac that became the paradigmatic mood enhancer. “Prozac” has come to stand for a whole group of similar antidepressant drugs and is used as a kind of shorthand.

While the first pharmacological antidepressants were developed in the 1950s and 1960s, *Prozac* was the first of a whole new class of drugs: the selective serotonin reuptake inhibitors (SSRIs). The SSRIs were developed in the 1970s and had far less side effects than previous antidepressants. Prozac was first marketed in 1987; it instantly became a huge success and was welcomed as a kind of wonder drug. In 1994, only 7 years after its release, Prozac was the second best-selling drug worldwide.

The popularity of Prozac and other SSRIs as “lifestyle” drugs was probably increased by the 1993 book *Listening to Prozac*, in which psychiatrist Peter Kramer described how some of his patients used Prozac and came to feel *better than well*. They did not just recover from depression, but some of them also felt like certain character traits had been improved. They reported, for example, feeling less shy, more outgoing, more active, more enthusiastic, and more in control. Some even reported finally feeling like themselves. “This is who I am. I just feel strong. I feel resilient. I feel confident” (Kramer 1993, p. 219). Kramer coined the term “cosmetic psychopharmacology” to describe these effects. His book not only led to an increase in the popularity of Prozac but also started off the ethical debate.

Throughout the 1990s and 2000s, the sales of SSRI antidepressants kept rising. From 1999 to 2000, the sales of antidepressants in the United States saw a 20.9 % increase, to a figure of $10.4 billion, maintaining their position as the best-selling category of drugs (Elliott and Chambers 2004, p. 5). From 2000 onward, however, more critical reports on these drugs started to appear, questioning their alleged safety and lack of side effects. It gradually became clear that there were side effects, especially the increased suicide risk in children and adolescents using them was hotly debated in the scientific literature. Also reports of Prozac causing outbursts of

aggression and violence in rare cases started to appear, and the use of SSRIs was even presented by the defense as a mitigating factor in violence and murder trials (Healy et al. 2006). Moreover, the actual effectiveness of these drugs for the treatment of depression was increasingly questioned. A number of meta-analyses, especially the ones taking also data from unpublished trials into account, suggested that the effect of SSRIs on depression was far less than it had been believed to be (Kirsch 2010). According to some influential critics, SSRIs have only little more than a placebo effect on most people; they are not effective in mild or moderate depression and only have limited effects on people with serious depression. The type of enhancement effects on character traits and mood of more-or-less healthy people that Kramer described has never been shown to exist in a research setting – although insufficient research has been done here to make definitive claims (de Jongh et al. 2008; Repantis et al. 2009).

From being a wonder drug and the paradigmatic "mood enhancer" that sparked the ethical debate, Prozac has now become a highly contested medicine. Not much is left of the idea that pharmaceuticals can enhance mood and personality traits of healthy people as they desire. As known from the field of sociology of expectations, the high hopes and the hype that is often created around new technologies can in turn elicit a response of resistance, fear, and rejection. This dynamic can create a very polarized debate between proponents and opponents of a new technology or application that is not based on actual facts and knowledge. This seems to have happened to some degree in the mood-enhancement debate, where some of the enhancements that have been discussed – e.g., the adjustment of character traits according to one's desires or the delivery of instant happiness – have turned out to be of a rather hypothetical nature. This does not necessarily take away from the validity and importance of some of the philosophical and ethical arguments that have been made, though.

Since the mid 2000s, the ethical debate on pharmacological enhancement has turned in large part away from mood enhancement and towards cognitive and lately also moral enhancement. Some new emerging neuromodulation technologies, such as Deep Brain Stimulation (DBS), Transcranial Magnetic Stimulation (TMS), Vagal Nerve Stimulation (VNS), or Direct Current Transcranial Stimulation (DCTs), can trigger the same type of questions, however. These technologies are being tested in the area of depression, and they seem to have a potential to also enhance mood and perhaps certain character traits in healthy people. Especially DBS, with its potential to elicit manic and hypomanic states in patients, may be seen as a new type of "mood enhancer." The advent of these technologies may revive the mood-enhancement debate in the near future. At this point in time, it is difficult to predict how exactly these new neuromodulating technologies will develop. The history of SSRIs, which started out with high expectations and a hype but turned out to be at best a set of reasonably effective medicines for severe depression, and at worst "*The emperor's new drugs*" (Kirsch 2010), poses a warning against exaggerated expectations.

Be that as it may, discussions on how we should conceptualize mental problems, what the place for pharmaceuticals in dealing with such problems ought to be, and

how we should understand ourselves in relation to both mental problems and the proposed medical solutions for these problems remain important and topical.

Philosophical and Ethical Issues in the Mood-Enhancement Debate

A number of ethical and philosophical issues have come up in the debate on mood enhancement. These include worries about safety and side effects of psychopharmaceuticals, issues of justice, and fairness, who will have access, who will pay; but since these are not very specific for mood enhancement, they will not be dealt with here. The most important issues in the debate, and the most specific for the enhancement of mood and character traits, are those about the nature and value of happiness and human well-being; authenticity, identity, and the self; and the proper role of medicine and the medicalization of psychological states and traits, including the worry that the use of pharmaceuticals will divert attention from underlying personal or societal problems.

The Nature of Happiness

Is happiness initiated by a pill true happiness? Is it not somehow artificial and fake, of lesser value than real happiness? But what is real happiness and what contributes to true well-being? This is one of the primary concerns that mood enhancement by means of pharmaceuticals – or other neurotechnologies – raises.

Perhaps the most appealing illustration of this concern is the use of Soma in Aldous Huxley's Brave New World. In Brave New World everybody is engineered to do exactly what they are supposed to do and everybody is happy and content. Illness and misfortune have been banned, and people's lives revolve around pleasure and consumption. The drug Soma is widely used to help people feel good and to keep them content in this perfect world. "And if ever, by some unlucky chance, anything unpleasant should somehow happen, why, there's always soma to give you a holiday from the facts. And there's always soma to calm your anger, to reconcile you to your enemies, to make you patient and long-suffering" (Huxley 1994/1932, p. 217).

Given the dystopian features of Brave New World, it is no surprise that opponents of mood enhancement frequently invoke this image as a deterring example. The President's Council on Bioethics, for instance, uses it to illustrate "the debased value of a spurious, drug induced contentment. Soma – like cocaine, only without side effects or addiction – completely severs feeling from living, inner sensation from all external relations, the feeling of happiness from leading a good life" (President's Council on Bioethics 2003, p. 294).

Robert Nozick's well-known thought experiment of the Experience Machine has been invoked to discuss this issue and to explain why mere contentment or happy feelings may not be what we should be striving for with mood enhancement. The experiment shows that we want *reasons* to be happy and not just *causes* of happiness. We want our happiness to relate to things that actually happened, things we actually have done, or that are out there in the world and not just be caused by some pill or some machine (Schermer 2011; Kahane 2011; Liao and Roache 2011). This boils down to an argument against a hedonistic view of well-being; it shows that a happy mood is not enough for, or identical to, overall well-being, to having a good life, or to human flourishing.

Another way to make this point is to show that certain kinds of suffering may actually be essential parts of our moral lives and even of what it means to live a good life. Suffering from grief at the loss of a loved one, for example, is not the kind of suffering or the kind of negative emotion that one should want to "get rid of" by means of a mood enhancer (President's Council on Bioethics 2003; Olsen 2006). This implies that the relationship between so-called mood enhancement and well-being is much more complex than the simple idea that brightening one's mood will make you better off.

The Value of Alienation and Discontent

Another related point of critique on mood enhancement as a simple erasure of unhappy feelings and alleviation of discontent has been eloquently voiced by Carl Elliott (1998, 2003, 2004). According to Elliott, the problem that Prozac or other mood enhancements address is not so much depression or anxiety but spiritual emptiness and alienation. This alienation – which can be of a personal, cultural, or existential nature – is a symptom of Western (especially American) culture and points at deeper problems with giving meaning to life, finding a purpose, and making sense of the world we inhabit.

Using Prozac or other means to alleviate feelings of alienation does not address these deeper issues; it does not answer metaphysical questions of meaning, of who we are, or who we should be. According to Elliott, Prozac is not the answer because it wrongly defines the problem as a psychiatric one instead of an existential issue of meaning and alienation. "Imagine an accountant living in Downers Grove, Illinois who comes to himself one day and says, 'Jesus Christ, is this it? A Snapper lawn mower and a house in the suburbs? Is this all life has to offer to me?'" (Elliott 1998, p. 180). Should this man take Prozac to relieve this predicament and his feelings of alienation and being discontent with his life, Elliott asks. Should a doctor prescribe it for these reasons, to help people relieve their feelings of dissatisfaction, alienation,or meaninglesness? Elliott's suggestion is that there may be other and better ways to deal with such existential questions.

A somewhat related point of critique is that of social quietism: whereas discontent, unhappiness, or alienation could be reasons to try and change the social or cultural circumstances that cause them, taking pills to improve mood will only advert attention from those societal issues. This is also depicted by the role of Soma in Brave New World: it is distributed to the masses like bread and circuses to keep them quiet and content.

Authenticity and Identity

The issue that has raised the most extensive and fierce philosophical debate in the context of mood enhancement is that of authenticity and personal identity. Ever since Peter Kramer suggested that Prozac might not only enhance mood but also affect character traits in a favorable way, the question of what this does to the personal identity and the authenticity of the person using such drugs has been on the agenda. One of the most remarkable findings of Kramer was that his patients reported feeling actually *more themselves* when they used Prozac than without it. Can a drug bring you closer to "who you really are"? Can it enhance authenticity? Or do pharmaceuticals and other technological means that change personality traits in an artificial way make one less truly oneself, or a less authentic person?

Although proponents and opponents in this debate seem to agree that authenticity is an important value, they do use different accounts of what authenticity is (Parens 2005; Bolt 2007; Levy 2011). Some seem to refer to a notion of a true core self that lies hidden somewhere to be discovered; it refers to a way of life that is uniquely and truly our own. Others consider an authentic personality something that one has created and shaped oneself, that is not static but evolves over time. The difference boils down to seeing authenticity as either a matter of self-discovery or of self-creation.

Carl Elliot is one of the most important authors who have claimed that psychopharmaceuticals can threaten a person's authenticity. According to him, the use of such drugs may make you lose touch with who you really are. "It would be worrying if Prozac altered my personality, even if it gave me a better personality, simply because it isn't *my* personality. This kind of personality change seems to defy an ethics of authenticity" (Elliott 1998, p. 182). Elliott also points to the social pressures and the drive to conform to social expectations and norms and that is behind the use of these kinds of drugs. These drugs help people live the kind of life that is considered normal, appropriate, and successful by society and to adapt to the patterns and standards required for that – without questioning these norms themselves. A similar idea is expressed in this quote from Brave New World: "I don't understand [. . ..] why you don't take Soma when you have these dreadful ideas of yours. You'd forget all about them. And instead of feeling miserable you'd be jolly. *So* jolly" (Huxley 1994/1932, p. 82). The answer Bernard, the protagonist, gives to this question clearly refers to a notion of authenticity: "'I'd rather be myself,' he said. 'Myself and nasty. Not somebody else, however jolly'" (Huxely 1994/1932, p. 80). The basic idea that many people would agree with is that being yourself is a good thing even if this self is not in every respect perfect or agreeable.

The opposing view has been most forcefully argued for by David DeGrazia (2004, 2005). DeGrazia denies that there are any core characteristics that are somehow inviolable, that if changed, would render us inauthentic. According to his view, we may use psychopharmaceuticals or other means to help us change our traits to become who we want to be, as long as the choice to do so is autonomous. Pharmaceuticals can help us to shape and create our personalities, which is something we have always been doing anyway: we try to give form and direction to our lives and to who we are. Whether we use technological tools like pharmaceuticals to achieve this does not really matter. What matters is whether the changes are autonomous: whether the person in question wants them and truly identifies with them. Moreover, in order to be authentic, one should also be honest towards others about who one really is and not pretend or deceive them. “Any self-creation project that is autonomous and honest is ipse facto authentic,” he states (DeGrazia 2005, p. 112). So according to DeGrazia and others who follow this line of reasoning, if a person autonomously chooses to use mood enhancers to alter a certain aspect of himself, if people use them to bring their personality in line with who they truly wants to be, this can contribute to their authentic self-creation.

“Aspirin for the Mind” and the Mechanization of the Self

Contrary to the position of DeGrazia sketched above, some authors have argued that it *does* matter which *means* one uses to change mood or character traits. They claim that there is a significant difference between using means that are responsive to reasons, like psychotherapy, and means that work in a purely “mechanic” way, like pharmaceuticals. By using techniques that “bypass” reason or rational capacities to change traits, moods, or emotional responses, we regard persons in an overly mechanistic way, according to this line of argument (Freedman 1998; Levy 2007; Svenaeus 2009; Kahane 2011). Using pills to “cure” unfavorable emotional states makes them seem like simple headaches, without any meaning or content. However, emotional states, character traits, and behaviors are related to reasons and meaning and should not be treated with a mere “aspirin” but in a way that engages reason. What is ultimately at stake here, according to Carol Freedman, is “the perception of ourselves as responsible agents, not machines” (Freedman 1998, p. 136).

Against this point of view Neil Levy has argued that at least in certain cases, pharmaceuticals are used to change or cure emotional states or responses that, according to the person herself, have no rational ground. “We bypass her rational faculties, but we do so to treat an illness that in itself, by her own reckoning, bypasses reason” (Levy 2007, p. 117). If, however, pills would be used to create a happy mood without there being any reason for us to be happy, one could argue that the mechanization concern was valid – and here the argument touches on the previous discussion about the nature of true happiness and the Experience Machine.

Another refutation of the mechanization concern is that mood enhancers may not merely make one “feel good” without any reason but that they actually make one more

responsive to reasons. By changing our general affective orientation, they may help us to better appreciate the things that we have indeed reason to appreciate (Kahane 2011).

Medicalization

A final cluster of moral concerns about mood enhancement regards the question of whether we are talking here about the treatment of medical problems or disorders or whether it is enhancement of healthy people beyond their normal or natural selves – and if so, whether that is morally problematic. In order to answer this question, we would need to know how to distinguish between normal and pathological mental states or between mental health and mental illness. This is, however, notoriously difficult especially in the area of mental health since what we should regard as "normal" forms of mental functioning is to a significant degree determined by our cultural and historical context. Many contributors to the enhancement debate have argued that concepts of health and disease are inadequate, contested, and value laden and that it is therefore impossible to use them as the basis to distinguish between treatment and enhancement. Others have argued that this distinction is irrelevant altogether.

The boundaries between the domains of health and illness, normal and abnormal, tend to be flexible and shift over time, and this causes doubt about what we *ought* to regard as normal and abnormal, healthy, or pathological. In the mood-enhancement debate, concerns have been raised about the progressive extension of the boundaries of medicine and psychiatry and the further medicalization of emotional and social problems, which perhaps should be treated in different ways than with medication. Examples often referred to are the medicalization of shyness and the expansion of the diagnostic category of attention deficit hyperactivity disorder (ADHD).

What used to be seen as (extreme) shyness – constant anxiety in the presence of others, avoidance of social contact out of fear for others – has over the past decades come to be seen as mental illness: social phobia, social anxiety disorder, or avoidant personality disorder (Berghmans et al. 2011). SSRIs are used to treat these conditions. According to critics, this is the medicalization of a normal phenomenon, the pathologization of a social problem that should be solved in a different way, for example, by acceptance, by lowering our standards and expectations, or by training self-confidence. Likewise, the criteria for diagnosing ADHD have expanded over the years and have come to include more and more children, as well as adults. Children or adults who were previously seen as chaotic or easily distracted or overly energetic are now seen as having a disorder. Especially when these traits stand in the way of optimal performance, medication is prescribed to improve functioning. According to some this is a form of medicalization of underperformance (Schermer and Bolt 2011).

With mood disorders, a similar thing has happened. Not only have the meaning of and diagnostic criteria for "depression" changed and expanded over time, the indications for the use of antidepressants have expanded as well. Apart from their indication for major depression, SSRIs are also prescribed for anxiety disorders,

panic disorders, obsessive compulsive disorders, bulimia nervosa, and premenstrual distress. Moreover, there is also a significant amount of off-label use, i.e., the prescription of drugs for reasons that are not officially approved indications, like psychosocial problems, conflicts at work, marital problems, grief, or stress. One might call this the medicalization of unhappiness.

Authors who use the term medicalization in a pejorative sense do not always make clear why medicalization is problematic, especially not whether, and if so, why it should be considered as *morally* problematic. One reason to consider it as such is that medicalization may lead to the neglect of less harmful, cheaper, or otherwise better problem-solving approaches. Another reason concerns the safety and proportionality of risks and benefits when drugs are used for increasingly milder problems. Finally, it may lead to individualization of social problems and thus to unjust "blaming the victim" (Schermer et al. 2009). One of the causes of the increase in ADHD diagnoses may well be the increasing performance pressures on children at school and on adults in the workplace, and the increasing complexity and bustle of present day society. By labeling those people who have difficulty in keeping up the pace as "having a disorder," they are made to be the problem, instead of society. This may also place the focus of attention on solutions that affect the individual, instead of his social surroundings. For example, children who would do fine with some extra attention and smaller classrooms may now be given ADHD drugs instead.

Disease Mongering and the Role of Industry

A special role in the process of medicalization is played by the pharmaceutical industry, and much of the criticism on medicalization in the mood-enhancement debate has focused on this role (Healy 2004). Manufacturers of pharmaceuticals can exploit the blurred boundaries between what is normal and pathological and market their products as treatments for newly discovered or underrecognized disorders instead of selling them as enhancements, or so critics argue. Or as David Healy has claimed, in order to sell pharmaceuticals, one needs to sell diseases. The activities by which companies actively help to create new disease categories and "sell" sickness to create new markets are known as disease mongering. It has received ample attention and critique over the last decades, both in medical journals and public debate. The amounts of money spent on the marketing of SSRIs as well as the attempts of the pharmaceutical industries to present research outcomes in a more favorable light than may be warranted by the actual data are part of this process.

In part, the moral problems concerning disease mongering are the same as those concerning medicalization. Moreover, making a profit from medicines that are unnecessary and may cause harm is obviously morally problematic, as is manipulating research data. The ethical debate here turns not so much on the moral principles, norms, or judgments regarding such practices, as on the empirical substantiation of the allegations against the pharmaceutical industry.

Goals of Medicine

A final and related issue is whether mood enhancement belongs to the proper tasks of the doctor and whether it fits in with the goals of medicine. While treating diseases and disorders seems obviously to belong to the goals of medicine, there has been discussion about whether enhancing people's well-being or enhancing certain personality traits in the absence of pathology should also count as a goal of medicine. Would that not be drawing the boundaries of medicine too wide? While some argue that medicine should restrict itself to dealing with health-related problems, others believe that the "goals of medicine" may well include, or come to include, the enhancement of well-being (Brülde 2011; Synofzik 2009). Recent guidelines by the American Academy of Neurology suggest that some professional organizations indeed tend to accept enhancement as a part of medicine.

Anyway, the strength of the "goals of medicine" argument is limited; as Parens (1998) and others have argued, even if "the goals of medicine" could dissuade *doctors* from providing certain drugs, because they consider them enhancements rather than treatments, they provide no reason to forbid or forgo the use of such pharmaceuticals altogether. Other professionals might step in, or the distribution of such drugs could be left to a free market. A final pressing question then remains: how should such drugs be regulated, and should they be reimbursed by healthcare insurance schemes? This, however, is a topic that is by no means specific to *mood* enhancement and therefore will not be discussed further.

Concluding Remarks and Future Directions

The discussion on the ethics of mood enhancement fits into the wider debate on human enhancement, but it is also a debate on how we as human beings should understand ourselves, and how we should deal with our emotions and our own limitations, and what it means to have a good life. The discussion frequently touches upon the ways in which neuroscience and neurotechnologies are affecting our ideas about who we are and how we should understand ourselves, whether we should see mental problems as pathologies of the brain or as existential issues about meaning. Perennial philosophical questions about happiness, well-being, identity, and agency are all essential to the debate, as are more "mundane" questions about the power of institutions like medicine or the pharmaceutical industry.

While at present it appears as if the discussion on mood enhancement has subsided a bit – there have been no recent breakthroughs in either the mood-enhancement techniques or in the ethical arguments presented – this might change again in the future as new techniques like TMS or DBS become more widely available. Moreover, it seems likely that a broader range of emotions, mental dispositions, traits, and behaviors will be opened up for interventions, partly because of the developments in neurobehavioral science and partly because of the increasing importance that optimal mental functioning has in modern societies. The term mood enhancement may well become obsolete since what is at stake can be more aptly

described as “Biomedical Behavior and Emotion Regulation.” But whatever we are going to call it, the philosophical, ethical, and social questions discussed here under the flag of mood enhancement are here to stay for the coming decades.

Smart Drugs: Ethical Issues

Contents

Abstract

This chapter provides an overview of the debate regarding the use of so-called smart drugs – drugs originally developed for medical purposes, which are used to improve "normal" human cognitive function. Following a brief summary of the currently available empirical data, it focuses on three areas that have been and continue to be most controversial: questions of definition from philosophy of medicine, ethical issues for individuals, and ethical aspects of smart drug use for society.

Introduction

"Smart drugs" refer to pharmaceuticals that are taken not to treat a particular illness, but to "enhance" cognitive function beyond what is usually considered normal in humans. As such, they are one example of what has come to be called (medical) enhancement, that is, the application of medical technologies and interventions to improve or optimize human capacities and traits. Medical enhancement is nothing new; examples of the nontherapeutic – for example, spiritual – optimizing application of medical technology can be found as far back as the Stone Age. The unprecedented increase in medical options available to affect human characteristics and abilities over recent decades offers more options to "perfect" humans, but the activity as such and the desires behind it are far from novel.

Smart drugs are examples of what has summarily often been called "cosmetic psychopharmacology" (a term coined by Peter Kramer, e.g., Kramer 1993). The term "smart drugs" is to some degree problematic, because it can be seen to carry the connotation that the drugs in question are themselves "smart" or that it is indeed "smart" to take them. However, with this caveat, it will nonetheless be used in this article as a neutral term and alongside the more technical phrase "pharmaceutical cognitive enhancement." The expression "smart drugs" helps to highlight that this type of enhancement does not include other medical, nondrug technologies to improve cognition, e.g., training and nutrition to "boost brainpower," or the application of transcranial magnetic stimulation (TMS), deep brain stimulation (DBS), or brain-computer interfaces (BCI) to that end (but see "Cross-References"). It also denotes that the improvement that is aimed for applies to cognitive function and not personality, mood, or morality, which are other forms of cosmetic psychopharmacology (see "Cross-References").

The ethical implications of the use of smart drugs have not only fast become one of the biggest issues in academic neuroethics and indeed bioethics; they are also a favorite topic in the popular media. Recently, there has been criticism of "hype" around smart drugs. Studies show that evidence of the prevalence of use as well as the positive effects of smart drugs is routinely overstated in news articles, while the relative paucity of data on benefits, as well as potential side effects, are often underplayed (Partridge et al. 2011; Forlini and Racine 2009). The state of evidence on effects and prevalence is also ignored in some of the academic bioethics literature (Boot et al. 2011; Quednow 2010). This can, in turn, lead to what has been termed "speculative ethics" in other contexts (Nordmann 2007), where arguments are being developed based on unrealistic assumptions or expectations and conclusions drawn that have little bearing on reality.

It is one of the goals of bioethics to stay abreast of current trends and developments in both science and society, so that potential ethical problems can be anticipated or are at least not overlooked or ignored. Partly with this in mind, an attempt will be made in the following to present a balanced account of the ethics of pharmacological cognitive enhancement. As part of this effort, however, it is necessary to give at least a brief and general overview of the empirical background; owing to the scarcity of space, this should by no means be taken as exhaustive.

The Empirical Background

What Are Smart Drugs?

From caffeine to cocaine, there are very many pharmacological agents that can have the effect of altering and sometimes improving cognitive function, several of which have been around for a long time (for overviews, see, e.g., Nutt et al. 2007; AMS 2008). This contribution focuses on a group of drugs that share a number of characteristics: They have been developed for medical use, at least initially, and have therefore, at least to some degree, been studied by the usual means of medical research, for example, randomized controlled trials (RCTs); they are in current use as prescription drugs to treat neurological, psychological, or psychiatric conditions and are as such and in these applications legal in most countries; and they are often taken to be safer and have fewer side effects than common recreational, illegal drugs (such as cocaine). These are the drugs that debates about smart drugs or pharmacological cognitive enhancers mostly refer to. The best-known ones are modafinil, methylphenidate, and some amphetamines such as Adderall (see Table 77.1).

Frequency of Use

These drugs can be used off-label (not as part of a therapy of one of the described conditions) by healthy people with the aim to improve attention, wakefulness, alertness, concentration, working and long-term memory, cognitive control, spatial planning, and other cognitive functions – that is, they might be used as cognitive enhancers when preparing for and undertaking exams and tests, writing papers, and managing tiredness, stressful and long work days, high-pressure professional situations, etc. Media reports as well as academic articles often paint a picture of this being a "widespread" or "common" practice, particularly in some populations, such as college students, and some professional groups such as pilots, academics, and scientists, with use reported in the ballpark of 20–30 % in some groups (Chatterjee 2006; Sahakian and Morein-Zamir 2007; Anon 2009; Roxby 2011, meta-reviews Ragan et al. 2013; Smith and Farah 2011). Due to the perceived urgency of an "enhancement epidemic," this in turn has lead to an intense debate around the ethical and social implications of this use for individuals and society and calls for policy making and regulation.

Recently, there have been systematic studies evaluating the available evidence on the prevalence of use of pharmacological cognitive enhancers (the newest and most exhaustive ones are, e.g., Ragan et al. 2013; Smith and Farah 2011). These report that there is still a lack of reliable, representative data on enhancement use and most studies have methodological weaknesses; often these are the studies that report high numbers of users. Most of the evidence available comes from the USA; there has been less activity to study the use of smart drugs

Table 77.1 Smart drugs discussed in this contribution

Modafinil	Modafinil, which is sold under the trade names of Vigil or Provigil, is a stimulant that is approved in many countries as a treatment for narcolepsy. It is also used to treat shift work sleep disorder and excessive daytime sleepiness associated with obstructive sleep apnea. The exact work mechanism is still unclear
Methylphenidate	Methylphenidate, best known under its trade names Ritalin or Concerta, also a stimulant, is an established treatment of attention deficit-hyperactivity disorder (ADHD) approved in many countries. It is also used in some countries to treat narcolepsy and as an additive or augmentative treatment for depression. The main work mechanism can be described as inhibiting the reuptake of the neurotransmitters dopamine and noradrenaline/norepinephrine (Heal and Pierce 2006), leading to higher levels and utility of these in the brain
Amphetamines	The best known of these is the stimulant Adderall, a composition of several amphetamine salts, which is used in the treatment of ADHD and narcolepsy. It is approved for these indications in the USA, but currently not in Europe. While the exact work mechanism differs from methylphenidate, it also acts as a reuptake inhibitor of dopamine and norepinephrine/noradrenaline

in other parts of the world so far. What quality evidence is available does not support the diagnosis of cognitive enhancement via drugs as a widespread "epidemic" in need of urgent attention. While pharmacological cognitive enhancement appears to be a real phenomenon, for example, among students, evidence suggests that actual prevalence rates are far lower than reported in popular and some academic media and range between 5 % and 15 %, with the highest rates in college students and among some professional groups and the lowest in lifetime prevalence of use in general populations (overview in Smith and Farah 2011 and Ragan et al. 2013). Ragan et al. also highlight that rates might be lower than 5–15 %, because some of the studies, for example, conflated different types of use (e.g., use for recreational purposes) or did not distinguish between use for enhancement and use simply without prescription. European studies are rarer and very different in type, but rates seem to be even lower than in the USA; in a survey of a representative sample of the German working population, less than 1 % of the employees reported that they had used stimulants at least once in their lives against tiredness and sleepiness or for better concentration (DAK 2009). Another large German study among pupils and students showed lifetime prevalence between 0.8 % and 1.6 % (Franke et al. 2010). In a UK study, 0.5 % of staff and students of a University reported having used stimulants "to study" (Holloway and Bennett 2012), while a Belgian study reported that 4 % of a large student sample reported stimulant use during exam periods (Rosiers et al. 2010, cited in Ragan et al. 2013). In sum, while there is evidently some prevalence of pharmaceutical cognitive enhancement particularly in younger populations still in education, this is not a common practice.

Evidence of Effectiveness and Side Effects

All three drugs that are the focus of this contribution have been studied with established medical research methods, including double-blind RCTs. Results of enhancement effects drawn from these studies, as evaluated in recent systematic meta-analyses (Repantis et al. 2010; Smith and Farah 2011; Ragan et al. 2013), are, in sum, inconclusive and ambiguous and on the whole smaller than is often reported; most studies also report only on single-dose application and application in situations not resembling real life.

In an extensive meta-analysis, Repantis et al. did not find consistent evidence for a cognitive enhancement effect of methylphenidate, with the exception of a positive effect on memory (especially working spatial memory). Their meta-analysis could not verify a positive effect of methylphenidate on attention. It did verify such an (moderate) effect in modafinil, but no effects on memory or motivation. There was also evidence that modafinil maintained wakefulness in sustained sleep deprivation, but did not simultaneously preserve attention and executive functions. At the same time, there was evidence of "overconfidence" and "overrating" of performance in sleep-deprived subjects. Repantis et al. question whether increased wakefulness without maintenance of cognitive function coupled with overconfidence made the application of modafinil a practical enhancement when taken with the aim to stay alert yet preserve cognitive performance at pre-sleep-deprivation levels. Generally, effects, when found, were more pronounced in sleep-deprived subjects than in healthy, rested subjects and in those with low baseline performance to begin with. This was also supported by Smith and Farah, who report some positive effects on cognitive controls in subjects with low performance and high impulsiveness, but only mixed or none for others. Smith and Farah also report positive effects of stimulants on long-term learning and memory consolidation and mixed or no results on working memory and other cognitive functions. Overall, they conclude that the enhancing effects of the stimulants in question appear to be small. Ragan et al. report similar findings, adding that personal accounts from media and online stories about real-world application often describe bigger results than those found in academic studies. This might be due to a placebo effect or to individual differences.

Side effects of smart drugs are not often reported systematically (Ragan et al. 2013). When available, reports of side effects from studies also often translate poorly into the real world, where single-dose application under controlled circumstances is rare. In most evaluated studies, the drugs in question were well tolerated, with no severe side effects. Typical side effects included headaches, dizziness, gastrointestinal complaints, tachycardia, palpitations, nervousness, sleep disturbances, insomnia, and anxiety, but these led only infrequently to dropouts (Repantis et al. 2010). Most authors agree that the stimulants are not virtually side effect-free, as is routinely reported, but do have moderate side effects. However, severe side effects appear to be rare. An exception of this could be negative psychological and personality effects, for example, on the disposition to addiction or behavior towards other people, as reported anecdotally (Guardian student blog 2012), but this is so far unclear.

In view of these empirical results, some authors have questioned whether we are actually facing a problem of smart drug use and its consequences that is significant enough to warrant the current large scale debate (Quednow 2010). However, foregoing discussion could preclude informed argument of a real phenomenon that might, after all, be emerging and thus change and develop in the future. At this stage, it appears that the most sensible approach towards the issue of smart drugs is to continue efforts to get better data and evidence, particularly on real-world prevalence, benefits, and effects, and continue having a sober, evidence-based discussion of the real and likely potential ethical and social implications of their use, mindful of the danger of simplistic argument, hype, and premature policy conclusions.

Ethical and Social Issues of Pharmacological Cognitive Enhancement

The following section provides a brief overview of some of the issues and arguments discussed in the debate around the ethics of smart drugs for cognitive enhancement. As mentioned, this has become a very active and large debate and it is impossible to do full justice here to all the subtleties of the many sub-discussions or to provide comprehensive referencing. The aim is instead to highlight some of the main lines of argumentation. It should also be noted that several of the issues discussed are not specific to pharmaceutical cognitive enhancement, but apply to other forms of medical enhancement as well.

There are many ways to structure an overview of the issues around smart drugs, but a common approach is to distinguish between questions that raise (1) issues of philosophy of science and medicine, (2) ethical questions stemming from actual or potential impacts of smart drug use on the individual, and (3) societal effects of smart drugs use.

Philosophy of Medicine: Treatment/Enhancement and Natural/Unnatural

Particularly in the earlier stages of debates around medical enhancement, many focused on the so-called treatment-enhancement distinction, which is also relevant to the issue of smart drug use (e.g., Daniels 2000). To name just one example, there are cases of severe ADHD where Ritalin is clearly the treatment of an illness, and there are clear cases of Ritalin use for enhancement outside of any medical context, such as use by professionals to give them an edge the morning before a big presentation. However, there are also cases that fall into a grey area between the two, such as the application in a child with a possible ADHD diagnosis who was doing badly in school. Is this treatment of an illness or an unethical “quick-fix” enhancement? (Singh 2005).

To broadly summarize the arguments from the debate around the treatment-enhancement distinction, particularly in medical decision and policy making, it is

sometimes assumed – often implicitly – that a clear line can be drawn between the treatment of a medical condition and an enhancement that does not aim to cure or ameliorate disease. It is further taken that this line automatically establishes what is ethically permissible, appropriate, or even mandatory to do, either in the clinical field by doctors or more generally by policy makers. However, it has been pointed out that to draw such a line is quite impossible, owing to the fact that the underlying concepts of normality, illness, and disease necessary for the distinction are themselves disputed, unclear, and/or leave grey areas of definition (Buyx 2008). For example, many activities undertaken in preventive medicine and public health are not aimed to cure an illness, but in fact to improve or optimize bodily functions beyond "normal" (i.e., heighten the body's ability of immune response via vaccinations) (Juengst 1997). There is also a continuum of interventions to improve cognitive function starting from "brain training" to exercise to drinking coffee to using smart drugs to brain surgery, and just because some of these can (also) be used to treat illnesses, this does not make them ethical as such (Singh and Kelleher 2010). Similarly, it has been stressed that even if a clear line between treatment and enhancement could be drawn, it would not be possible to draw normative conclusions just from that (Daniels 2000). After all, just because an intervention is clearly defined as not treating an illness, it does not follow that it is therefore unethical or, as others claim, an ethical imperative. In order to argue one way or the other, additional arguments are necessary, for example, about the proper goals of medicine; about what constitutes desirable and undesirable cognitive and other human traits, functions, and capabilities; or about individual or societal harms and benefits of psychopharmacological enhancement (Wolpe 2002; Harris 2009; Galert et al. 2009). This latter line of thinking has been dominant lately among those writing academically on the topic; while the debates on the best definition of concepts such as health and illness continue, efforts to demarcate enhancement and treatment in a definite way have largely subsided in recent years.

Another line of argument, throwing into relief the question what the fundamental categories, terms, and concepts of science and medicine mean and what their normative upshot could be, centers on the "naturalness" or, rather, "unnaturalness" of cognitive enhancement (e.g., Daniels 2009). Some argue that "human nature" should not be tempered with; in most of the bioethical literature on pharmacological and other enhancement, this is not framed as a religious argument (although it could be), but by reference to the fact that it is ethically superior to accept what is "given" instead of striving for what is "made" (described in Parens 2005). This is mostly coupled with additional arguments, such as concern over asymmetrical relationships between generations (e.g., Habermas 2003), but at the heart of the argument lies an understanding of nature or naturalness as imbued with particular moral value. The standard response to this is that nature is not a normative concept as such and just because something is natural, it does not mean it is superior to something "made"; neither are natural states of affairs always preferable to changes to nature (Birnbacher 2006). Nature is not benevolent, and the whole enterprise of medicine could be viewed as intervening into a "natural" course of life.

While not presupposing a strong normative idea of what is natural and therefore ethical and right, others point to a natural character, particularly in children, which it would be preferable to let unfold without pharmacological cognitive enhancement (Brock 1998); this could also be framed as an argument from safety (see below).

The debates around the normative force of categories such as “illness” or “natural” are likely to continue (see, e.g., Stein 2012), but at least with regard to cognitive enhancement, a consensus seems to have been stable for some time now that for an ethical appraisal, other issues have to be taken into account.

Ethical Issues for Individuals

Safety, Efficacy, and Risk/Benefit Assessment

Like any medical intervention, enhancement poses questions of both safety and efficacy. Smart drugs have been developed for and trialed on clinical populations with diagnosed disease and there is, as pointed out, still a lack of evidence on how they work and what risks they pose in those not so diagnosed. The current evidence seems to indicate that short-term, direct physical risks are fairly minor, but that the desired positive effects might also be quite small. Due to an absence of data, it is unclear to assess to what extent smart drug use poses long-term risks, and there are some concerns that the psychological effect on individuals (e.g., with regard to addiction), currently reported mostly on an anecdotal level, could be significant (Heinz et al. 2012). In view of this uncertainty, it would be premature to denounce smart drug use as generally unsafe and risky, but it would be equally unsound to declare it to be unproblematic in terms of safety. This situation alone warrants great caution with regard to use in children; in adults, the uncertainty should be taken into account before use is recommended as, for example, a moral obligation (Harris 2009, see also Boot et al. 2011).

In terms of an assessment of the risks versus the benefits on an individual level, another controversial ethical question is whether different risk/benefit ratios are acceptable when evaluating enhancements in healthy adults as opposed to treatments of adult patients. Depending on the illness, higher risks might be deemed acceptable in patients when they are the price of treating an illness, while risks should be lower in anything available to healthy people. The opposite view could also be taken: While patients as a vulnerable group need special protection from risks that are too high, healthy and autonomous adults should be free to choose enhancement with high risks (Greely et al 2008). It is obvious that this question cannot be answered even by reference to the best evidence; it leads directly into thorny issues of individual choice and autonomy, as set out below. Again, children constitute a special demographic; most agree that in exposing them to the still uncertain risks of smart drug use, particular caution should be exercised, due to the fact that their brain is developing at a particularly high level and the need to avoid unnecessary medication (Singh and Kelleher 2010).

Autonomy and Consent

Whether a person should be free to use smart drugs, judge their benefits, and assume their risks is the question which lies at the heart of many discussions around the ethics of smart drug use. Sketched broadly, how this question is answered depends on whether the decision to take smart drugs is regarded as an autonomous choice or not. In liberal societies, there is broad agreement that as long as a person's choice is fully autonomous, it is his/hers to make, and going against his/her choice amounts to unwarranted (and sometimes illegal) paternalism. A choice is usually deemed autonomous when it is made by a person who is, at the time, fully able to make choices (i.e., he/she is in possession of his/her normal cognitive capacities), who is fully informed about risks, benefits, and alternatives, and who is under no undue pressure or coercion (see classic text by Faden and Beauchamp 1986). Under such circumstances, a person is taken to be able to give informed consent (the established tool to ensure autonomous choices within the medical sphere). There are those who argue that an adult person who has full mental capacity is the only one to decide whether he/she can reach his/her goals in life – a successful career, feeling less stressed and tired, etc. – best by using pharmacological cognitive enhancement. As long as he/she does not harm others and as long as he/she is informed about what is currently known about risks and benefits, he/she should be free to use smart drugs anytime he/she wants. Even if evidence on potential harm is still lacking, he/she should be able to judge whether he/she is willing to assume that his/her smart drug use could have unforeseen consequences. On a strong version of this view, he/she should also be free to harm himself/herself, in case future evidence shows that smart drug use does indeed lead to significant harm. On this view, any policies that ban or regulate smart drug use would be inappropriate, because they interfere with autonomous, private decision making of individuals (Bostrom 2008).

Opponents of this view usually do not deny the right to make autonomous choices, but question whether the decision to enhance cognition is truly autonomous. In view of the lack of reliable evidence and some documented misinformation in the media about the benefits and risks of smart drugs, it could be questioned whether those using smart drugs can in fact be regularly assumed to be fully informed. It is also argued that in societies with a lot of emphasis on achievement and success, people might feel pressured to enhance themselves or might be persuaded or indirectly coerced by employers or educators to use smart drugs. The reasons given for smart drug use in empirical studies often have to do with gaining an edge over competition or with being able to adapt better to competitive environments; some authors worry that students and people in professions where having cognitive abilities beyond normal range might be an advantage, such as in soldiers and pilots, could face some indirect coercion (Hyman 2011). While there is so far only anecdotal evidence that, e.g., pilots on long-haul flights or soldiers operating drones remotely are expected to use smart drugs in order to stay awake and alert for long times, peer pressure or simply the need to be able to keep up with colleagues already using smart drugs might become more common should smart drug use spread (Greely et al. 2008).

The higher prevalence of smart drug use in students is also seen as an illustration of the fact that competitive environments might exert subtle pressure to use any means available, including pharmacological “helpers,” to succeed, thus impairing fully autonomous decision making (The Danish Council on Ethics 2011; Sandel 2009).

Again, with children, the situation is different, insofar as parents are the legally responsible decision makers. Most drug use in children occurs within the medical sphere, and many have discussed rising numbers of children being prescribed Ritalin and other psychopharmaceuticals for ADHD (e.g., van den Ban et al. 2010), with some worrying that diagnoses are widening too much. Evidence shows that adolescents and young adults, on the other hand, are groups that engage in smart drug use for enhancement purposes outside of medical settings, for example, pupils in secondary schools. The question whether adolescents make autonomous decisions about this use of smart drugs is a pressing one, and there are calls to provide this demographic with special protection, even while the issues of whether adults should be free to enhance themselves by any means they want are being discussed (Singh and Kelleher 2010).

In sum, the complex discussion around autonomy and informed consent is still ongoing and reflects underlying debates between more individualistic, liberal interpretations of how individuals should be able to make choices and those views that point out systematic and structural challenges to personal free choice in modern societies. Often, whether a call for regulation of smart drugs is issued or not depends on how the view about autonomy is combined with arguments about social impacts of smart drug use, which will be discussed below.

Personality and Authenticity

As mentioned briefly above, some are concerned that using smart drugs may alter people’s personalities. Arguments along these lines can currently not be clearly proven or disproven by evidence, but in view of the fact that personality and authenticity are considered vitally important concepts for humans, the issues discussed under these headings should be duly considered (an excellent overview of the arguments with many references is Parens 2009; see also Gordijn and Buyx 2009).

Psychopharmacological enhancements, including smart drugs, face the charge that by using them, people change their personality in that they become less authentic. (The question of authenticity is closely linked to the aforementioned debate around autonomy; indeed, authenticity could be understood as an element of autonomy.) A popular version of the authenticity argument states that for a person to be authentic, he/she must be “true to himself/herself” and feel that his/her experiences and feelings are “his/her own.” Critics of cognitive enhancement fear that by altering cognitive states through drugs, people become alienated from their own feelings and experiences and separated from the world as it really is (President’s Council 2003; Elliott 2003). Users of enhancement who have used smart drugs could be seen to have taken a shortcut through technology. They may achieve a desired goal, such as better test results or work performance, but they can no longer be described as having achieved it *themselves* nor can they claim the experience as *their own*. Hence they lose awareness of who they are and what the world is truly like.

However, others have pointed out that this criticism relies on a specific understanding of authenticity (Gordijn and Buyx 2009). An alternative view would be to regard being authentic as living a life of self-fulfillment and self-creation. It has been reported that people feel alienated from their own life and experience precisely because they are not able to behave or do what they feel would fit best with the idea they have of their own personality (De Grazia 2005). On this view, cognitive enhancement could be a way to bring someone closer to the way they would like to be – better able to focus, more alert, etc. – thus making them more instead of less authentic. Cognitive enhancement could thus be regarded as a tool people utilize to achieve abilities or states which they believe are part of who they truly are and which they otherwise have difficulties to realize and experience (De Grazia 2005, for a discussion see Gordijn and Buyx 2009).

Social Aspects of Smart Drug Use

A number of arguments are brought to bear on the debate that focuses on – currently largely potential – effects of widespread and/or unregulated use of smart drugs on society. Usually, these are not harnessed by those authors who put forward a strong autonomy view, but rather by those who point to systematic or social barriers to fully informed, free decision making when it comes to pharmacological cognitive enhancement. Their more "relational" focus on the individual situated within society seems to lend itself to a greater emphasis on social aspects.

Issues of Justice

A central concern is whether unrestricted/unregulated smart drug use could lead to more inequality between individuals and more unequal societies (Greely et al. 2008, Hyman 2011). It is well-documented that traditional tools that are considered helpful to improve personal achievement and success – e.g., additional tutoring and professional training, opportunities to network, and meditation – are more available to those already privileged within societies. First of all, knowledge of the methods is usually spread widest in well-off groups such as professionals, academics, and ambitious college students. In societies that foster academic and professional competition, access to knowledge about how to gain a competitive edge and how to be better in the workplace is a valuable currency and not equally distributed across all social groups. Moreover, like other tools to improve cognitive abilities, smart drugs, if supplied on the free market, cost money. Thus there are those who worry that if the already privileged improved themselves further through the use of pharmacological cognitive enhancement, the less fortunate could fall even more behind, leading to a highly divided and unequal society, with "super achievers" at the top end and "normals" at the bottom. This has moved some to call for a ban or at least strict regulation on smart drug use and other forms of enhancement (The Danish Council of Ethics 2011). However, others have responded to such thoughts differently: Famously, some have argued that smart drugs (and other medical enhancement) could also be used to compensate for some of life's unfairness,

if those who are disadvantaged or less endowed with marketable cognitive skills were given access to them. On this view, smart drugs would be targeted specifically at and provided to those who are underachieving, for example, through a publicly funded health-care system or in schools, to help underprivileged students (Buchanan et al. 2000). Again, this is an ongoing discussion, which will most likely benefit from further research on actual social impact of smart drug use as well as further discussion on how issues of justice could be translated into public policy (see, e.g., Dubljevic 2012).

Changes to Society: Medicalization and Disengagement

Some of the issues mentioned in section "The Empirical Background" can also be framed with regard to their social effects. In societies that value success and competitiveness, with learning and work environments that encourage achievement and that are structured around high performance at particular times in order to advance (e.g., student placement tests, entry exams), some fear that smart drug use, if deregulated, could become widespread. This in turn could lead to a number of potential negative effects not only on individuals and their ability to make free and informed choices but also on societies (Danish Council of Bioethics 2011): Standards of normality could shift if significant percentages in certain groups used smart drugs. Attitudes towards conventional human abilities could change in the long term, with average abilities becoming less the norm than a negative exception. Some are concerned that people could become afraid that their normal traits are fundamentally inadequate (e.g., Sandel 2009). As a result, cognitive enhancement could trigger a medicalization of thus far ordinary human abilities.

Another effect on society which is discussed negatively is a variation of the authenticity concern mentioned above (as well as of the old adage "no pain, no gain"). If significant numbers of people enhanced their cognitive abilities and took a "shortcut" to better concentration, higher alertness, and better memory, would they still get the same satisfaction from their achievement, or would this lead to a devaluation of hard work and generate less engagement with the world? (Danish Council of Bioethics 2011, see also Parens 2009) It has been argued that widespread cognitive enhancement could lead to a society where fewer people became active in civic institutions (President's Council 2003). Others have pointed out, using analogies from professional sports, that enhancement corrupts the "rules of the game" and makes it pointless (Sandel 2009); seen in this light, smart drugs could be a means to corrupt the rules of cognitive achievement and professional success, which would be particularly troubling if some of the justice concerns materialized at the same time.

Conclusions and Directions for Future Research

On most of the ethical issues concerning the individual, discussions are still ongoing and it is quite likely that in different countries different conclusions

will be drawn, which might lead to differences in policy making with regard to access and regulation or deregulation of smart drugs. In some countries, policies around the medical prescription of the drugs in question are being clarified. However, these will be applicable mainly to the medical field of practice and will therefore not address many of the issues this contribution has focused on, which occur mostly outside of medical practice. Off-label use, somewhere between the treatment of illness and cognitive enhancement purposes, remains in a regulatory grey area, as does use that aims for enhancement from the start. Thus there is a need not only for continuing debates and research around the issues sketched in this article but also for far more consideration of the question if and how these issues could be tackled by and translated into proportionate and effective governance and policy (Bostrom and Sandberg 2009; British Medical Association 2007).

The same holds for the social effects described above. In some earlier criticism of smart drugs, potential social effects of pharmacological cognitive enhancement were expressed quite strongly without reference to their mostly speculative nature, and there was a danger of painting a picture of very negative consequences of a phenomenon that was – and to some extent, as described above, still is – in its rather early stages. However, this does of course not warrant a dismissal of the concerns around social effects, especially when regulation and policy are considered. Whether deregulation would lead to increasingly widespread use and whether that in turn could have some problematic effects on society are reasonable and important questions for both ethicists and policy makers to ask. Cognitive enhancement by other means than the drugs discussed here is not novel, nor is drug use as such. Looking at similar developments in the past and present could help point out areas of justified concern and of unwarranted overanxiety. At the same time, it would be desirable to see more specific empirical work done on potential social effects of smart drug use to fill in the existing gaps in the available evidence; certainly, the introduction of any future policies that regulate access to smart drugs would need to be accompanied by research on related individual as well as social impacts.

Ethics of Brain–Computer Interfaces for Enhancement Purposes

78

Fiachra O'Brolcháin and Bert Gordijn

Contents

Abstract

This chapter outlines two key ethical issues associated with the possible development of brain-computer interfaces (BCIs) for enhancement purposes. Following a brief introduction to brain-computer interfaces, a scenario in which their use for enhancement purposes becomes commonplace is sketched. General ethical issues associated with the widespread adoption of brain-computer interfaces for enhancement are then introduced. The concept of privacy is presented and various issues surrounding this concept are discussed. BCIs are likely to create new challenges in relation to informational privacy and psychological privacy. These challenges are explored, particularly in relation to liberty,

autonomy, personal identity, psychological well-being, and safety. It is recommended that the privacy of future BCI users is protected. Following this, the related concept of autonomy is introduced, and various issues surrounding this concept are examined. The manner in which BCIs are likely to impact autonomy is explored, with a particular focus on freedom, brain hacking, and the transfer of autonomy. Due to the moral significance of autonomy, it is recommended that restrictions are placed on the development and availability of certain types of BCIs.

Introduction

Brain-computer interfaces (BCIs) are systems that connect a person's brain with a computer and an external device. A BCI detects electrical signals in a person's brain via electrodes attached to the scalp, inserted onto the cortical surface, or via intracortical electrodes. The computer component then interprets these signals, translates them into commands, and sends these commands to the external device. In effect, BCIs enable users to control external devices with their thoughts. BCIs have developed quickly over the past few decades (Wolpaw et al. 2000). The World Technology Evaluation Center's (WTEC) report (Berger et al. 2007) on BCI development provides a comprehensive overview of research in the field. Initially, BCIs were designed for therapeutic purposes in order to help people with severe physical impairments (e.g., paraplegics or people with locked-in syndrome) to interact with the world as well as to improve the functionality of artificial limbs. Lately they have made their way into the gaming industry to enhance the interactivity of games-entertainment systems, as well as being of interest to the automotive and robotics industries (Berger et al. 2007). Their use for gaming, cars, and robotics illustrates the potential for enhancement. After all, with BCIs users can move things around exclusively with the power of their thoughts without moving a single muscle, thus extending normal motor abilities. In the chapter at hand, enhancement is understood in a very broad sense as the extension of human capabilities and skills (including capabilities to play and to imagine) that are already within the normal range beyond the standard scope. The current development of BCIs for enhancement purposes demonstrated that this technology has the potential to be used beyond the therapeutic realm. A change from BCIs only being used by a very small percentage of the population – severely impaired patients – to a state in which they are commonplace or even ubiquitous (much like the rapid adoption of personal computers and mobile phones) and are being used for enhancement purposes would present new ethical issues. After a brief sketch of some of these issues, the focus turns to two ethical issues associated with BCIs for enhancement purposes: privacy and autonomy. Both privacy and autonomy are likely to be significantly and directly affected by BCIs. An examination of these issues seems timely. It would seem only prudent to have regulations in place prior to the widespread adoption of BCIs. First though, a potential development of BCIs into a future technology with a widespread use

for enhancement purposes will be sketched. This will provide the basis for an analysis of the ethical issues associated with this scenario.

The Scenario: Widespread Use of BCIs for Enhancement Purposes

BCIs were originally developed for therapeutic ends. By translating electrical brain activity into commands that can be interpreted by a computer, BCIs have been successful in allowing severely paralyzed people to control computer cursors and external devices connected to the computer (Pires et al. 2012; Lopes et al. 2013), including robotic arms (Minati et al. 2012).

More recently, BCIs have been designed for enhancement purposes as well. They have, for example, been developed for entertainment purposes (Nijholt et al. 2009), and a number of these BCIs have already entered the market, such as the Emotiv EPOC, the NeuroSky, and the intendiX SOCI. BCIs are also likely to have military applications, with the US Department of Defense previously having shown some interest in developing the technology (McGee 2007). In addition car manufacturers have begun to research the technology to aid drivers in controlling their vehicles (EPFL 2011). There is also the possibility that BCIs will be used to interact with "Smarthomes" – homes in which information technologies are integrated with the appliances and systems so as to enable communication between them. In such homes the systems, appliances, and environment will be able to respond to electronic commands (Edlinger et al. 2011). Neurofeedback uses electroencephalography (EEG) or functional magnetic resonance imaging (fMRI) to provide information about a user's brain activity. Neurofeedback is used to "train" the brain, in order to help it function better, for instance, to encourage relaxation (Plass-Oude Bos et al. 2010). Neurofeedback has also been used in therapeutic contexts.

As BCI technology develops and becomes cheaper and more sophisticated, more and more enhancement applications are likely to be found and their commercial potential exploited. If they continue to develop at their current pace, they might very well be a prevalent feature of society in the future. Enhancement BCIs could be extremely useful in day-to-day living, as your thoughts could control your vehicle or the devices in your home. The evolution of augmented-reality headsets (such as Google Glasses)[1] might also be combined with BCIs so that the Internet display in the headsets could be utilized via thought rather than voice command. BCIs are already being used for entertainment purposes, as mentioned above; so it seems possible that they will begin to merge with virtual reality technologies in order to provide the brain with experiences that will seem real.[2] For instance, a virtual reality headset that can "read" brain activity would be able to

[1]Augmented reality refers to scenarios in which the real, physical world is overlaid with computer-generated imagery or information, accessible via a device such as a mobile phone or Google Glasses.

[2]Indeed, virtual reality theorists have argued that the brain does not easily distinguish between the real and the virtual on a perceptual level (Blascovich and Bailenson 2011).

respond not only to the user's commands but to their subconscious thoughts, adapting the virtual world to enhance the user's experience and enabling the user to interact with the world without the necessity of having to use a mouse or keyboard. Significantly, the BCI would also have a record of the brain activity of the user. Besides enabling users to directly connect to the Internet, BCIs might perhaps even facilitate communication directly from brain to brain (cf. Gordijn and Buyx 2010).

The widespread adoption of BCIs for enhancement purposes is plausible. The phenomenal development of computer technologies means that BCIs may well become cheap and easy to use. Competition between extremely wealthy technology firms suggests that the economic conditions for their development exist, and market demand for personalized computer devices suggests the public has an appetite for novel technologies.

Ethical Issues Regarding BCIs for Enhancement Purposes

There are broad ethical concerns surrounding the harms and benefits of BCIs and their impact on society. They also have interesting ethical implications in relation to responsibility, privacy, and autonomy. This chapter will focus on privacy and autonomy and only briefly mention the other concerns. Regarding the harms and benefits of BCIs and their impact on society, it is difficult to avoid speculative claims, while the impact of BCIs on responsibility has been explored more comprehensively elsewhere (O'Brolcháin and Gordijn forthcoming). Firstly, some general ethical issues associated with BCIs are explored before concentrating, in the next sections, on privacy and autonomy.

Responsibility: Assuming that BCIs become more generally used, there are some serious issues of responsibility to be resolved. It is unknown, thus far, how easily people will be able to control external things via their thoughts. There is a possibility that training and licenses will be required. Also, the allocation of responsibility for the actions of a BCI-controlled device will be far more complicated than ascribing responsibility for normal bodily actions as the computer interpreting the brain signals and transmitting them to the device adds an extra layer in the causal chain of events determining any action the user intends. As such, the question of whether the device is "integrated into the self-concept and the structures of decision-making and acting" (Clausen 2008, p. 1497) needs to be determined. Even then, there exists the possibility of the transmission of the user's intent being garbled or misinterpreted by the computer, known as the responsibility gap, a phrase originally advanced in relation to the increased use of computers in everyday life and essential systems (Matthias 2004). This concerns the problem of allocating responsibility for the actions of a machine or device that uses genetic algorithms or some form of learning to change behavior in a way that is neither predictable nor altogether controllable. The result is that it might be difficult to ascribe responsibility to the user of the device. While Tamburrini argues that situations may arise when neither the user nor the programmers or designers of

a BCI can be held morally blameworthy for a damaging act performed by a brain-actuated mobile device (Tamburrini 2009), others (Clausen 2009) (Holm and Voo 2011) (Grübler 2011) question the significance of the responsibility gap. For instance, Grübler argues that the lack in causal control does not hinder the ascription of moral responsibility, while Clausen (2009) argues that the responsibility gap is not a practical problem in relation to BCIs as certainty regarding actions is not always necessary for ascribing responsibility.

Nonetheless, it will be imperative to determine the ways in which BCIs respond to subconscious brain activity and how responsibility will be allocated in such scenarios. The potential of hackers to utilize BCIs to either control the device or, more speculatively, the person, would seriously reduce responsibility – a person whose device has been hacked cannot be held responsible for the actions of this device; if a hacked device could be used to control a person via manipulation of their brain states, then this person could not be held responsible for "their" actions. However, if BCIs increase access to information and a person's ability to process it, then a person might be held responsible for more of their actions, given that they would have more information about the likely outcomes of said actions. Finally, BCIs might aid the allocation of responsibility (assuming the responsibility gap problem can be overcome) in that records of brain activity created by the BCI and aid investigators in determining the intentions of a user (see O'Brolcháin and Gordijn forthcoming, for a more detailed analysis).

Harms and benefits: It will be important to ensure that the use of BCIs has a positive balance of benefits and risks. Certainly, in the cases of therapeutic use of BCIs, the benefits are obvious and may appear to outweigh the risks in many scenarios. The greater autonomy offered by BCIs to those with locked-in syndrome (LIS) or who are severely paralyzed will be of enormous benefits to such people. There are ethical problems surrounding the obtaining of consent from LIS patients, as it is difficult to determine to what extent such patients are able to signal their consent or otherwise. Patients would suffer harm if the researcher misinterprets ambiguous signals in a manner favorable to their research. Moreover, raised expectations of patients regarding the capacities of BCIs might result in harmful disappointments (Haselager et al. 2009). Other harms include the risk of infection resulting from the interface, hacking, as well as threats to responsibility, autonomy, and privacy. The proportionality of the benefits and harms of BCIs-for-enhancement purposes is less clear-cut. First, there is the risk that people might find BCI use addictive. This would be particularly relevant where BCIs are used for entertainment purposes, as a BCI in conjunction with virtual reality glasses might provide experiences that are so immersive, certain people might prefer the virtual world to their own regular lives. BCIs that directly stimulated the auditory, visual, and tactile centers of the brain would be able to provide deeply immersive experiences. Using neurofeedback, such entertainment BCIs, would be able to adjust settings of the experiences they provide in response to the user's brain state. This last scenario would be more likely if BCIs were combined with other technological developments such as virtual reality goggles and/or some form of direct brain stimulation (Lecuyer et al. 2008). Then there might be long-term detrimental

neurological effects, which are currently still unknown. It would be wise to undertake long-term studies of the neurological effects of regular and repeated use of BCIs. Furthermore, the ease of access to huge amounts of information facilitated by BCIs can be a source not only of benefits but also of harms. The benefits of being able to access information from external sources (feedback from the ambient environment, Internet sources, and, possibly, drones) are obvious. However, the availability of such information might consume a great deal of our attention. Indeed, such an abundance of information might reduce our need, and hence ability, to think critically or evaluate the worth of various sources of information.

Detrimental societal impact: Broader societal changes must also be considered, although these are much harder to assess in advance. For example, BCIs may provide their users with significant advantages that those without these gadgets lack, leading to further inequalities in society. Those with BCIs might be able to access information more quickly, assess situations with greater lucidity, and interact with more of the environment than those without. Then there is the possibility that a society might become over-reliant on using BCIs, with the result that those without BCIs might find it difficult to participate in social and institutional life. For example, if ambient environments become commonplace, BCIs might be essential for interacting with them. Thus those without BCIs will risk exclusion, with consequent social and psychological risks. There may of course be more unintended consequences that cannot easily be foreseen, particularly if BCIs are used in conjunction with other enhancement technologies, virtual realities, or (should they come into existence) artificial intelligences.

However, in this chapter the focus is on two ethical issues for which BCIs almost certainly will have important implications, privacy and autonomy. While societal impacts and harms and benefit are harder to predict, it is extremely likely that privacy and autonomy (along with responsibility) will be directly affected by BCIs.

Privacy

Concept

As ICT advances it comes into greater and greater conflict with conceptions of privacy. Biometric identification uses eyes, faces, and fingerprints to identify individuals. Infrared scanners are capable of gathering information about the interior of a building; the proliferation of satellites in the skies and cameras in our cities allows populations to be watched; Internet firms such as Google and Facebook profit from gathering information about their users; mobile phones can be used to track an individual. Security fears, commercial interests, and a love of convenience have meant that contemporary society has begun to accept the erosion of privacy. On the other hand there is growing awareness of the dangers of such a development.

Widespread adoption of BCIs would add a new dimension to existing privacy threats. As mentioned, the computer in a BCI interprets a person's brainwaves and translates them into commands that are transmitted to the external device. Consequently, the computer will create a record of these signals. In the future, as BCIs become more sophisticated, they might possibly enable a record of people's intentions, emotions, and thoughts. Currently of course, a record of thoughts would be impossible – BCIs presently only enable limited actions, such as the movement of a cursor on a computer screen or the sending of steering directions to a car. To repeat, however, as BCIs grow in complexity and as the relation between brain activity and thought is better understood, BCIs may enable the creation of a record of the user's thoughts, emotions, and intentions. The computer component of the BCI is required to translate brain signals to the device, whatever it may be. As a result, a record of that brain activity will be kept. Depending on the accuracy with which specific brain signals can be interpreted as thoughts, emotions, or intentions, the computer will be able to keep a record of these states. This might radically reduce the degree of privacy an individual possesses. However, it is first necessary to present an outline of the concept of privacy.

Privacy plays a role in the development of liberal thought, with both Locke (1689) and Mill (1859) defending the rights of people to a sphere from which the government was excluded. Locke, in his defense of individual rights, argues that governments are not permitted to interfere with a person's property, including the property in their own person (Locke 1689). Locke's insistence that a person's property must be free from interference without consent implies a respect for privacy. Certainly Locke would argue that a government has very limited rights to interfere with a person's body without their consent. While Locke focuses on property, Mill argues that liberty is of the utmost importance, as it allows people to develop their own capacities. As such, it is essential that governments and others are not allowed to interfere with the individual so long as the individual is not harming others (Mill 1859). Both Locke and Mill emphasize the importance, within a liberal society, of a space in which a person is free from interference, in short, a private space. While privacy is not identical with liberty, it is intimately connected with it.

In contemporary discussions it is important to distinguish different kinds of privacy. For instance, a distinction can be made between informational privacy (confidentiality, anonymity, secrecy), physical privacy (modesty and bodily integrity), and associational privacy (relating to sharing of intimate moments, i.e., during illness) (Allen 2011). It has also been suggested that there ought to be a category for psychological or mental privacy (Floridi 1999). This would concern freedom from psychological interference or intrusion.[3] Of course, it was initially supposed that

[3]The categories of privacy mentioned above plausibly overlap, particularly where BCIs are concerned. For instance, someone using a BCI to "hack" a mind would obviously breach informational privacy by gaining information to which they have no right. This information might also concern intimate relations of that person with another, thus, breaching associational privacy. Finally, from a materialist perspective, hacking the mind, removing some information from the brain is breaching a person's physical privacy.

psychological privacy was guaranteed in part because of others' inability to access the contents of the mind. With BCIs, of course, this assumption no longer holds. Our concern is with informational and psychological privacy, as these are the types of privacy most obviously affected by BCIs. Furthermore, while the majority of the above conceptions of privacy might be culturally specific and may not be valued in smaller-scale societies and may not always have been present historically, the privacy of thoughts, intentions, and emotions has thus far been a fact of human nature. That BCIs might affect this form of privacy is worthy of serious consideration.

Issues

There are a number of ways in which the use of BCIs might conflict with informational and psychological privacy. BCIs will most likely have some record of the brain activity of the user as the computer will need to interpret brain signals in order to translate and transmit them to the device. Depending on the sophistication of analytic techniques, such data will be available to determine what people are thinking, feeling, imagining, intending, and more generally experiencing from their own subjective point of view about at various times and in various situations. Currently people can be tracked via mobile phones and satellites, our interests can be determined through analysis of our purchases, and databases and social networks store much of our histories. Despite this, our thoughts remain private, accessible only to us and beyond the reach of others. BCIs, by keeping a record of the user's brain activity (and arguably their subjective experiences), make it far more difficult for the user to control who has access to the contents of their mental life and to restrict access to those contents. With a BCI, that brain activity and the information available as a result of it is technologically available. This evolution of technology will mean that there is a greater potential for practically private realms (i.e., the mind) to be accessed. The potential loss of informational and psychological privacy has implications for autonomy, dignity, and liberty.

Both the moral status and extent of privacy can be questioned, however. For instance, Persson and Savulescu (2012) contend that the moral right to privacy is doubtful. They argue that people gaining information about you *need* not change your state; it only involves a change in the state of those gathering the information. They claim that the moral right to privacy is not established sufficiently. They do hold that one might be entitled to expect privacy in practice, due to the existence of property rights (which they take for granted). If you do something within your own property, people would only be able to find out about it by violating your property. Hypothetically, people might be able to find out about your actions within your own house without violating your property by, for instance, developing telepathy or X-ray vision. So, they argue that citizens cannot demand, as a matter of moral rights, that other people do not gain specific information about them. Furthermore, they hold that even if the knowledge that people might know something about you did involve an unpleasant change in your state (i.e., stress), this does not violate

a moral right. Moreover, they suggest that the remote probability of a grave threat to society could justify surveillance of its citizens if this can be done without violating other rights, such as rights to bodily integrity or the right to property (Persson and Savulescu 2012).

However, this stance is unconvincing. Privacy – particularly informational and psychological privacy – is important. This perspective is not uncommon. In international human rights law, privacy is generally considered to be a human right.[4] Furthermore, James Griffin (2008), for example, in his defense of human rights, argues that without privacy, autonomy is threatened and that therefore privacy should be considered a human right. Privacy is important for autonomy as the freedom from scrutiny, judgement, and pressure to conform supply the time and space in which a person can authentically choose how to live. He contends that because humans are social creatures people will self-censor (often unconsciously) if they feel that they are being watched. So if decisions about how to live were open to public scrutiny, then people's instincts for self-censorship and self-defense would come to the fore. Specifically, Griffin argues that the right to informational privacy – a provision that protects us against people's access to certain knowledge about us – can be considered a human right (Griffin 2008). Informational privacy "is a necessary condition of normative agency, and so is instrumentally valuable" (Griffin 2008, p. 236). Informational privacy covers data, conversations, and works of art if they are self-revealing (i.e., reveal the innermost thoughts and emotions of an agent) (Griffin 2008). Similarly, Thomas Scanlon contends that an account of privacy must protect a person's interests in not being seen or overheard or observed as well as the broader interests in which a person can carry out their activities without having to continually worry about other observers (Scanlon 1975). For Scanlon, the essential point is that there should be some system of limits to observation that is generally understood and observed. Privacy sets limits on the sort of information about you that others can use and the ways in which they can use it. Privacy is connected to the norms, conventions, and laws that protect us against certain kinds of offensive intrusions involving observation of our bodies, our behavior, and our interactions with other people. Moreover, Scanlon argues that privacy can be violated even if people are unaware of the violation (Scanlon 1975).

In creating new ways to challenge privacy norms, BCIs will alter the circumstances in which people can expect to enjoy privacy. The widespread use of BCIs would mean that every individual who uses a BCI is no longer certain of being free from scrutiny at the mental level. Their brain activities are potentially open to scrutiny as it may be possible to flash images before these people and record their brain responses. If this were done subconsciously (or while embedded in some form of entertainment), the user would not even notice. So companies and governments, as well as hackers, would have the potential to access information reflecting an

[4]Article 12 of the Universal Declaration of Human Rights (1948) says: "No one shall be subjected to arbitrary interference with his privacy, family, home or correspondence, nor to attacks upon his honour and reputation. Everyone has the right to the protection of the law against such interference or attacks" ("The Universal Declaration of Human Rights," 1948).

individual's thought processes. There are experimental results that demonstrate that it is possible to gain access to a user's personal details (e.g., banking information) using a BCI connection with a 10–40 % degree of accuracy (Martinovic et al. 2012; Anthony 2012). If BCIs do become more sophisticated, it is reasonable to suppose that hackers or other external parties might also become more adept at retrieving information from a BCI. This means that it will be impossible to guarantee the privacy of thought for the BCI user. Specifically, the ways in which BCIs will challenge privacy will have implications for other areas of ethical importance, such as autonomy, liberty, personal identity, psychological well-being, and safety.

Autonomy: The importance of privacy in relation to autonomy makes a strong prima facie case in favor of privacy. As mentioned above, without certain forms of privacy, people's instinct for self-censorship and self-defense would seriously undermine their ability to choose how to live their lives authentically. Thus autonomy is undermined. The knowledge that one is being, or the fear that one might be, observed is, in most cases, likely to alter behavior. Consider how people, in phone conversations and arguably in diaries, exercise some level of self-censorship – they realize that others might become aware of their views and opinions. So even a perceived lack of privacy *will* change a person's state. If it were possible to access a person's thoughts, people would be likely to attempt to exercise control over what they think about. BCIs will make it possible for others to have access to people's brain activity. BCIs would be even more invasive than reading a diary or eavesdropping, as a person could possibly gain access to subconscious thoughts as well as conscious decisions. This potential loss of psychological privacy might affect autonomy not only in terms of how people behave but also in terms of how they subjectively experience the world – a person, if they used a BCI regularly, would no longer be able to be certain that their brain activity (and, arguably, thoughts) were unobserved. This would affect peace of mind. BCIs may also provide a more direct method of affecting autonomy, which will be discussed below.

Liberty: The information produced by BCIs could also be used by those with malicious intent to impose restrictions on liberty. For instance, widespread use of BCIs will present opportunities for unscrupulous governments. Let us assume that the adoption of BCIs is voluntary rather than obligatory.[5] Suppose conditions exist in which the majority of the population regularly use BCIs and companies store and make use of the information gathered by these BCIs. In such a scenario, governments may well lay claim to this information, at least in situations in which a risk (i.e., a terrorist threat) exists. Google's transparency report reveals the number of requests it receives from government law enforcement agencies for users' private information.[6] More sophisticated research into BCI use might

[5]However, questions might arise regarding the voluntariness of the choices to use a BCI in a world in which the social and economic systems of society are designed for use with BCIs in a similar manner to the necessity, in many parts of the world, of access to the Internet. A society in which BCIs are the norm may exert enough pressure on people to use them that the choice cannot be considered voluntary.

[6]http://www.google.com/transparencyreport/

reveal correlations between dangerous or risky behavior and specific brain activity. Governments are likely to be interested in these correlations (the Los Angeles Police Department (LAPD) is already using "big data" techniques to predict future crimes[7]). If a government were to become convinced that the correlations between certain brain states and certain dangerous acts were convincingly certain, they might successfully pass legislation to enable "precautionary" or "preemptive" safety measures, i.e., detaining people with certain brain states. In principle, such preemptive measures could expand until certain brain activity or even thoughts are made illegal. "Thought crimes" could become a reality. Such a dystopia is obviously reminiscent of Orwell's *1984*. It may be unlikely, but its possibility makes a strong case for the protection of strong privacy rights for BCI users.

Personal identity: The privacy of thoughts is particularly important as it allows people freedom to think about their options, their lives, and their hopes and fears. That people's thoughts are inaccessible to others unless they wish to communicate them is a fact of human nature (thus far). It is impossible to know how people would be and how people would perceive themselves if thoughts, emotions, and intention were fully transparent. Private thoughts play a large role in people's conceptions of themselves, in who "they are," they are central to a subjective sense of oneself. Floridi's argument that a person's personal information is an important element of their personal identity (Floridi 2005) is even more persuasive in relation to BCIs and the information stemming from the operations of a person's mind. As such, the importance of private thoughts to our subjective sense of the self is therefore of great moral worth and deserving of protection.

Psychological well-being: A person's brain activity could be assessed to determine a person's response to various stimuli (i.e., landscapes, buildings, people, speeches, advertisements, political policies). It would certainly be possible for databases to keep track of people's brain states, either in a limited or unlimited form depending on what the BCI records. If third parties are able to access the databases, then there is a clear privacy risk. Many people might not wish their opinions of and responses to certain events to be known to anybody other than themselves. The possibility of others knowing what you think about a certain subject may well cause embarrassment or shame. Others would be able to find out information about how a person responds to various stimuli and, possibly, even how a user's subconscious mind operates. Even if private information is released without malicious intent, the results may be humiliating for the person and thus have a negative effect on their psychological well-being.

Safety: Other harms might, however, arise in a scenario in which BCIs are ubiquitous. For example, an observer might gain valuable information about the person and use it for self-serving or malicious ends by hacking into their BCI and

[7](see Morozov 2013)

extracting information the user wished to keep secret. The idea that there should be limits to observation not only protects the individual from embarrassing revelations but more importantly affords the individual protection from governments or other powerful interests. In the West, security fears appear to be stronger than distrust of governments, as Persson and Savulescu's argument demonstrates; but privacy must be of immense importance for those living under authoritarian regimes. The erosion of strong privacy norms in Western democracies would certainly help authoritarian regimes legitimate further invasions of their citizens' privacy as such regimes could claim they were behaving no differently than their democratic counterparts. The West would no longer provide an alternative model against which invasions of privacy could be measured.

Recommendations

Although BCIs are already in use, they are currently not widespread. This means there is an opportunity for legislators to put in place protections of privacy in relation to BCIs. BCI users should have control over their personal information and that they ought to be able to restrict all access to this information. Robust legislation would be required to ensure that BCI users may determine who has access to their information. Therefore, it is recommended that strong rules be put in place prior to the widespread adoption of BCIs. Legislators have an opportunity to learn lessons from the rise of social networking sites and Internet behemoths such as Google where legislation often lagged behind technological development, allowing such companies to set the agenda regarding privacy.

It is plausible that providers of BCIs will wish to lay claim to much of the information produced by the devices, in ways similar to the commercial strategies of Google or Facebook. It is worth remembering that there is no presumptive right to access this information. There is no reason to suppose that simply because I decide to buy and use a BCI that anyone else has a right to the information that this BCI records about my brain activity. The information produced by BCIs is more intimate and more integral to a person's sense of self than, say, their shopping habits, the musical preferences, and their political views. The information gathered by a BCI would encompass far more of a person's personality, including their subconscious patterns of thought. Claims to such intimate information, information absolutely integral to the person, fail to respect the autonomy of the person (in Kantian terms), using their personal information as a means (to increase profits or promote security) rather than respecting the person as an end. Without strong privacy protections, such instrumental perspectives on the person would be normalized.

Users will be free to sign contracts with providers, but it is recommended that privacy protections are put in place by governments prior to the contracts being created by the legal departments of BCI providers. If privacy protections are put in place prior to the widespread adoption of BCIs, any such claims to ownership of such intimate information would be easier to resist.

Autonomy

Concept

Unlike privacy, where there seems to be a lack of positive consequences, popular use of BCIs may have some positive as well as some challenging implications for people's autonomy. The concept of autonomy is philosophically complex. It plays a central role in both Kantian ethics (the rational will was considered by Kant to be autonomous and therefore capable of laying down moral laws so that the agent has authority over his or herself) (Kant 2005) and liberal political theory (Christman 2011). For John Stuart Mill, for example, it was imperative that "human beings should be free to form opinions and to express their opinions without reserve" (Mill 1859, p. 119), and in situations in which the customs or tradition of other people are the rule of conduct rather than the individual's character, "there is wanting one of the principal ingredients of human happiness, and quite the chief ingredient of individual and social progress" (Mill 1859, p. 120). Although he may not use the term, Mill is clearly emphasizing the value of autonomy. Arguably, then, autonomy is central to our conception of the agent and of normative agency, i.e. being able to deliberate and choose without external interference, manipulation or distortion.

A working definition of the concept of autonomy will be used. Autonomy can be understood as requiring authenticity or being one's own person, freedom, and a degree of knowledge about one's circumstances and regarding one's choices. In order to be autonomous then, a person will need to be able to choose for themselves how they wish to proceed; they will need access to relevant information in order to make these choices; and they will need a certain lack of constraints so that their autonomy is not hollow.

Issues

BCIs can be used to enhance aspects of autonomy in a number of ways.

Information: Access to information relating to choices is a key aspect of autonomy. BCIs can enhance an agent's capacities in this regard. Google has developed a headset that provides users with an "augmented-reality" display (as well as a camera, microphone, and GPS). The device is voice activated and allows people to access the web hands-free while going about their day-to-day life (Rivington 2013; Google 2013). It is easy to foresee how the designers of these (or similar) devices would be eager to combine them with BCIs. These could in principle provide a person with direct web access that is activated by thought alone. The knowledge available on the web would be easily available for inspection at all times. In this configuration BCIs could also provide more information about the physical world around us. The technology could connect to drones, cameras, vehicles, or to the ambient environment (a world in which networked devices are embedded in objects with the result that networks connect users and the networked

world around them), obtaining live feeds about weather or traffic or other dynamic systems. Future evolutions of this technology might perhaps even allow webpages to be sent directly to the visual part of the brain – to be presented to the "mind's eye." BCIs (in conjunction with various sensor technologies and other programs) could also be beneficial in assessing a person's health and making them aware of their situation and the impact of their choices by using records of their brain activity to help determine levels of, for instance, stress or concentration. The BCI would be able to keep a record of the actions of the person and how their brain responded. This might facilitate the creation of a "lifelog" in which the person's brain states were correlated with their actions and habits. This record could be used to provide the user with more information about themselves with which they could make more informed choices. The potential for BCIs to provide immediate access to realms of information far beyond the normal human range illustrates ways in which they might enhance a user's autonomy.

Freedom: Secondly, BCIs might increase freedom. Certainly the therapeutic use of BCIs, such as allowing paraplegics or those with locked-in syndrome to access the Internet, to control wheelchairs, or to control parts of their environment (most likely the devices in their houses) will significantly increase their autonomy. However, these uses ought not to be considered enhancement, since they aim at restoring a person to the normal range of human functioning. There are, of course, also ways in which BCIs might be used to increase human freedom for a person already within the range of normal human functioning. At the most basic level, a BCI would enable a person to manipulate parts of the external world – smart homes, drones, or robots from far afield – while leaving their hands free. Beyond this, users may be able to communicate silently with others, participate in more immersive computer games, and perhaps share mental experiences with other users. This is an increase in positive freedom – people will have a greater capacity to do more things in more ways; thus people will have more choice in how they wish to spend their lives. This could make a person's life both more interesting and more fulfilling. However, BCIs could also threaten autonomy in significant ways, namely, through brain hacking, the voluntary transfer of autonomy and coercion.

Brain hacking: BCIs rely on a connection between the user's brain and the device. This connection enables the user to send commands to the device. The existence of this connection suggests that it might be possible for commands or signals to be sent in the other direction – for a brain to be "hacked." Given that computer systems can be hacked, there is a risk that the computer system in a BCI could be hacked. If signals can be sent to the user's brain via the BCI connection, the victim might lose autonomy. Such signals need not be direct commands, it would be enough to disrupt a person's thoughts or change their state of mind or their responses to the environment for the person's autonomy to be violated. This might be done for commercial reasons in order to increase the likelihood of a person choosing one product over another. Such methods could also be used as a form of cyberwarfare; BCI connections could be used to disrupt the thoughts of users or possibly disable users. Moreover, it might be possible to utilize a BCI user's brain activity without their being aware of it. Consequently, they would be participating

in activities (facial recognition projects, data-mining projects, etc.) without their knowledge and consent.

The possibility of controlling rats via electrodes implanted in their brains has been demonstrated (Talwar et al. 2002). BCIs do not *require* the implantation of electrodes in a person's brain, but by opening a channel to a user's brain, BCIs might (in the future) pose a risk that a person could be controlled, especially when BCIs would have become much more sophisticated, picking up detailed information from many different specified regions in the brain, thus allowing sophisticated third-party intrusions into the brain. One of the more disturbing aspects of this is that the person might be completely unaware that they have lost complete autonomy. If the victim behaved in a way that was at odds with their long-term goals and past desires, they would (if they regained autonomy) be aware that they had behaved out of character. Yet there is no reason to necessarily assume that they would regain the degree of autonomy needed to make such a judgement. If hacking were a possibility, there would always be a fear that any apparently autonomous decision a person made was not, in fact, their own. This threat attacks one of the fundamental bases of moral agency – the idea that an agent is not only one who acts but who alone has authority over the initiation of their actions (Buss 2008). Obviously, if a person's brain is hacked, they will not have authority over the initiation of their actions. BCIs, if they enable other agents to initiate the actions of a BCI user, undermine the user's autonomy and therefore undermine the grounds of moral agency. It will no longer be an axiomatic truth that a user's will is their own.

Voluntary transfer of autonomy: Not only will BCIs enable third parties (potentially) to hack into another BCI user's brain and influence their mental life in that way but BCIs might allow a person to transfer their autonomy to third parties as well. If this were the case, authority over ourselves would cease to be inalienable. A person could allow another to access their BCI and thereby gain a certain degree of control over them. That people will be able to transfer authority[8] over themselves, possibly at the level of thoughts, desires, and values, means an intrinsic feature of our moral agency disappears, i.e., the necessity of the agent having control over their internal self. Philosophically, the development of BCIs that could enable such a transfer will impact on our understanding of the metaphysics of agency; on a more practical level, the possibility of ceding authority over oneself or of having authority over oneself removed will potentially alter social relations and power structures significantly. For instance, it is possible to imagine a loss of autonomy being used in punitive scenarios. In cases where a prison sentence is not deemed an appropriate punishment (or where prisons are overcrowded), a person could be required to wear a BCI so that their brain activity could be monitored and, potentially, manipulated.

Coercion to use BCIs: Finally, there is the question of whether the choice itself to utilize BCIs for enhancement purposes will truly be autonomous. It is worth noting

[8]Transferring authority over oneself might be attractive to members of religious cults or for erotic reasons, for instance.

that the idea that BCIs will enhance autonomy presupposes an individualist understanding of autonomy that can, at the very least, be challenged. Certainly, the prevalence of computers and mobile phones in contemporary society was not a decision voted upon by the global populace at large. On the one hand, it could be argued that individuals decided, more or less autonomously, to use these new devices. On the other hand, the changing social landscape also demanded that these new devices were adopted, as otherwise people would no longer be able to do their jobs or partake in the life of a society that required the use of such devices. So, while there is a degree of choice – prepare to do research using computers or look for another career; use a mobile phone or risk social exclusion – this choice is heavily weighted in favor of the adoption of the new technology. If everyone is able to access information instantaneously via a BCI, anyone without one will be at a disadvantage. If BCIs are needed to interact with an ambient intelligent environment and these environments become the norm, BCIs will be required. It could be the case that BCIs will form an integral element of a person's health record or be needed to drive a car.

Recommendations

Given the practical risks that BCIs pose for autonomy and the significance of autonomy in moral philosophy and liberal political theory, as well as the practical importance of autonomy, it would be prudent to ensure that they cannot be used to weaken or undermine autonomy. Firstly, the use of information gathered from BCIs will have to be regulated. The knowledge of the ways in which a person responds to various stimuli would make it far easier to indoctrinate or brainwash that person, thereby reducing their autonomy. Secondly, it will be necessary to ensure that BCIs do not enable the hacking of a person's brain. This might mean that nonmedical BCIs that can be accessed *by others* and used by them to directly change a person's brain states without that person's knowledge or consent do not enter the market. This is not to imply that there should be a complete ban on BCIs that change people's brain states; such a ban would be absurd. Many technologies, not to mention everyday actions, change people's brain states. The concern with BCIs relates to harmful changes, such as undermining autonomy, invading privacy, manipulation, addiction brainwashing, and loss of responsibility. As such, changes to brain states can be conceived as existing on a spectrum ranging from trivial to harmful. Empirical research will no doubt be needed to determine where on this spectrum specific technologies lie and which ones should be prohibited. Such a ban would place restrictions (for economic reasons) on how BCIs are likely to be developed. Very strong and reliable firewall technologies will have to be developed to avoid third parties exploiting the information pathways between brains and computers for intrusion purposes. Ultimately, the importance of autonomy, and the risk posed to it by BCIs that might enable hacking or brainwashing, ought to limit the types of BCI that enter the market.

Conclusion

The use of BCIs for *enhancement* purposes poses a number of threats. These threats will be present in cases where BCIs are used for therapeutic purposes too, but they will not affect society at large as there are proportionally very few people that require or will potentially require BCIs for therapeutic purposes. If BCIs for enhancement purposes become prevalent or even necessary in order to function in society (in a way similar to access to a computer), the threats outlined thus far will need to be resolved. The widespread use of BCIs for enhancement purposes would of course have real benefits as well. They are likely to provide a great deal of entertainment for people, allowing people to experience virtually anything. People using BCIs will be able to instantaneously access digital information, connect with other users, and interact with the Internet (or its future equivalent) very directly and ubiquitously. BCIs may also enhance people's abilities to process information and evaluate their own thoughts, desires, and motivations.

It is essential to consider whether the benefits offered by BCIs used for enhancement purposes are proportional. The risks – particularly the risks to privacy and autonomy – are severe. The possible undermining of autonomy and privacy will have significant effects on the moral and political landscape. Both autonomy and privacy are important for normative agency. In light of the threats to autonomy and privacy, the *enhancement* benefits of BCIs appear relatively minor. Access to information is already almost instantaneous if you have access to a computer or smartphone. If one is lucky enough to have time to indulge in entertainment, there is no shortage. Certainly, it appears that BCIs might be useful – they might make housework easier, driving safer, and communications faster. However, these benefits do not appear to be proportional to the risks posed. Certainly, any regulators valuing a liberal society, particularly one in which autonomy and privacy are highly valued, should be cautious about permitting widespread use of BCIs for *enhancement* purposes before adequate safeguards have been developed that can effectively and safely tackle the challenges to our privacy and autonomy.

Therefore, a number of recommendations regarding the ethical issues associated with widespread BCI use for enhancement purposes are offered. In relation to privacy, it is contended that if BCIs become a prevalent tool, it is essential that they are limited in the amount of information they can gather about the user, that it is clear who has access to this information, and that protections are put in place for psychological privacy. Ideally, this information would either not be stored or, at worst, would be aggregated and anonymous. In relation to autonomy, it is argued that there should be restrictions on the development of BCI technologies that might facilitate the reduction or even loss of the user's autonomy. Users will need to be sure that they are safe from hacking-type attacks or viruses that might affect their mental states via the BCI. Finally, we contend that study of the possible long-term benefits and harms (such as addiction, societal disruption, and safety) of BCIs is required.

The Morality of Moral Neuroenhancement

79

Thomas Douglas

Contents

Abstract

This chapter reviews recent philosophical literature on the morality of moral enhancement. It first briefly outlines the main moral arguments that have been made concerning moral *status* neuroenhancements: neurointerventions that would augment the moral status of human persons. It then surveys recent debate regarding moral *desirability* neuroenhancements: neurointerventions that augment that the moral desirability of human character traits, motives, or

conduct. This debate has contested, among other claims, (i) Ingmar Persson and Julian Savulescu's contention that there is a moral imperative to pursue the development of moral desirability neuroenhancements, (ii) Thomas Douglas' claim that voluntarily undergoing moral desirability neuroenhancements would often be morally permissible, and (iii) David DeGrazia's claim that moral desirability neuroenhancements would often be morally desirable. The chapter discusses a number of concerns that have been raised regarding moral desirability neuroenhancements, including concerns that they would restrict freedom; would produce only a superficial kind of moral improvement; would rely on technologies that are liable to be misused; and would frequently misfire, resulting in moral deterioration rather than moral improvement.

In recent years, a number of philosophers have become interested in the nature and morality of moral neuroenhancement. These are usually taken to be interventions that aim to augment, and (expectably) succeed in augmenting, the morality of an individual or one or more of her traits. This chapter follows recent literature in discussing only moral enhancements of *human persons* or their traits. The term "moral enhancement" is henceforth used to refer only to enhancements of this sort.

People have traditionally sought to morally enhance themselves through means such as introspective reflection, engagement with literature, or calm moral discussion with others, and to morally enhance others through rational persuasion, the application of incentives or disincentives, or moral education. However, prompted by developments in the cognitive sciences, much recent discussion of moral enhancement has focused instead on moral neuroenhancement. Moral neuroenhancement can be distinguished from more traditional varieties of moral enhancement by the fact that it operates by altering brain states or processes directly, that is, not by (i) modifying the agent's perceptually accessible environment (as in the application of incentives) or (ii) by engaging the agent's deliberative capacities (as in introspective reflection or rational persuasion). Paradigmatic examples of moral neuroenhancement would operate via the administration of drugs or application of brain modulation techniques such as electrical or magnetic brain stimulation.

Moral neuroenhancements all involve increasing the morality of an individual or trait. Thus, two natural ways of classifying moral enhancements are according to the *metric* by which morality is measured and the *target* of the enhancement – that is, the entity whose morality is augmented. Possible metrics of moral neuroenhancement would include moral status, moral considerability, moral responsibility, moral understanding, moral virtue, moral desirability, moral rightness, and moral permissibility. Possible targets of moral neuroenhancement would include the human person or his character, motives, or conduct. There are various ways in which one could combine different metrics and targets to describe different varieties of moral neuroenhancement. However, two kinds of moral neuroenhancement have dominated recent discussion of this topic, namely, (1) neuroenhancements of the moral status of humans (henceforth, moral status neuroenhancements or MSNs) and

(2) neuroenhancements of the moral desirability of human character traits, motives, or conduct (henceforth, moral desirability neuroenhancements or MDNs).

Two main kinds of question have been asked about MSNs and MDNs: questions about their possibility and questions about their morality. For example, there have been discussions of whether MSNs or MDNs are possible or likely to become technically feasible. There have also been discussions of when, if ever, it would be morally permissible, desirable, or obligatory to (a) pursue the development of technologies that would or might enable MSN or MDN, (b) undergo a MSN or MDN oneself, or (c) impose such an intervention on others.

This chapter outlines some of the main arguments that have been advanced concerning the morality of MSNs (section "Moral Status Neuroenhancements") and MDNs (sections "Moral Desirability Neuroenhancements" to "Further Questions"). Discussions concerning the possibility of MSNs and MDNs are touched upon where relevant to arguments concerning their morality but are not comprehensively surveyed.

Moral Status Neuroenhancements

Moral status neuroenhancements aim to bring it about that a human enjoys greater moral status than she would otherwise have enjoyed and (expectably) succeed in realising this aim. There is disagreement regarding how to understand moral status, but one way of understanding it is as a metric of the strength and breadth of moral protections (such as moral rights or claims) enjoyed by a being. Understood thus, moral status neuroenhancements could operate, for example, by conferring additional moral rights on humans.

Recent discussion of moral status enhancements has taken place primarily within debates on the morality of general cognitive or mental neuroenhancements (section introduction in ▶ Chap. 75, "Neuroenhancement" and ▶ Chap. 80, "Reflections on Neuroenhancement," ▶ Chap. 69, "Using Neuropharmaceuticals for Cognitive Enhancement: Policy and Regulatory Issues" ▶ Chap. 76, "Ethics of Pharmacological Mood Enhancement"). It has in large part been stimulated by a speculative comment offered by Francis Fukuyama in a 2004 critique of transhumanism, the movement most committed to human neuroenhancement. Francis Fukuyama writes that:

> Underlying [the] idea of the equality of rights is that we all possess a human essence that dwarfs manifest differences in skin color, beauty, and even intelligence. This essence, and the view that individuals therefore have inherent value, is at the heart of political liberalism. But modifying that essence is the core of the transhumanist project. If we start transforming ourselves into something superior, what rights will these enhanced creatures claim, and what rights will they possess when compared to those left behind? (Fukuyama 2004, p. 42)

One of Fukuyama's worries here is that enhanced beings might *claim* more rights than are enjoyed by unenhanced humans. But another concern is that enhanced beings would *actually have* more rights than the unenhanced. The latter concern can be interpreted as a concern that human neuroenhancement could result in the creation of beings with greater moral status than ordinary persons (call such beings status-enhanced beings or SEBs). This proposition has been the object of substantial subsequent analysis, most notably by Allen Buchanan (2009, 2011, 2012).

Why might neuroenhancement result in the creation of SEBs? The usual explanation draws on an analogy. It is often thought that ordinary adult humans enjoy higher moral status than at least some of our nonhuman mammalian relatives. In addition, it is often thought that our elevated moral status, relative to other mammals, can be attributed to our possessing greater mental capacity than other mammals. (Precisely which mental capacities confer higher moral status on us is open to dispute, but candidates include our capacities for self-awareness, rationality, and moral agency.) However, if we enjoy greater mental capacity than our mammalian relatives in virtue of our greater mental capacity, one might expect that beings whose mental capacity exceeded our own to a similar degree would enjoy greater moral status than us, and it might seem that the neuroenhancement of humans could, at least in principle, produce such beings.

The creation of SEBs would, it has been argued, be morally problematic since the existence of SEBs would be bad for ordinary persons (e.g., Agar 2012a). Arguably, ordinary persons could be permissibly harmed for the sake of these SEBs in ways that they may not be permissibly harmed for the sake of one another. For example, perhaps persons could permissibly be used, without their consent, in medical experiments designed to aid SEBs. Or perhaps persons could be rightly excluded from the democratic institutions of the SEBs.

Three main responses have been made to this line of thought. First, some authors have questioned whether human neuroenhancements could produce beings of greater moral status than ordinary persons. For example, Allen Buchanan (2009, 2011) and James Wilson (2007, 2012) argue for a threshold account of moral status according to which there is some level of mental capacity above which all beings have the same moral status, and beyond which ordinary persons already lie (see also Savulescu 2009; Wikler 2009). Buchanan invokes Stephen Darwall's (2006) work to argue that the ability to engage in practices of mutual accountability is what takes one across the threshold, while Wilson argues that a being has crossed the threshold if it possesses Rawls' two moral powers – a sense of justice and a "capacity to have, revise, and rationally to pursue a conception of the good" (Rawls 2001, p. 19). In reply, a number of authors have questioned whether there is good reason to prefer this threshold account of moral status to (a) a scalar account, according to which moral status is continuously rising with some aspect of mental capacity, or (b) a multi-threshold account, according to which there are multiple thresholds of mental capacity

making out differences in moral status, including at least one threshold that lies above the level of mental capacity possessed by ordinary human persons (Agar 2012a; DeGrazia 2012a; Douglas 2011a; McMahan 2009).[1]

A second response has been to argue that, even if human neuroenhancements could produce SEBs, this would not be bad for ordinary persons. Buchanan (2009, 2011) argues that persons already possess enough moral status to be *inviolable* and that this protects them against being exploited in the ways that those concerned about the creation of SEBs fear. For example, because persons possess enough moral status to be inviolable, they could *not* permissibly be used, against their will, in medical experiments designed to aid SEBs. However, it has been argued in reply that the inviolability enjoyed by ordinary persons is not absolute, so that SEBs could be more inviolable than us (Agar 2012a; Douglas 2011a; McMahan 2009). Thus, for example, when faced with a choice between killing an ordinary person and killing an SEB in order to avert some catastrophe, it might be permissible to kill the person but not the SEB. It has also been argued that the existence of SEBs might be bad for mere persons in ways that are unrelated to inviolability. For example, SEBs might have stronger claims to scarce resources, such as healthcare, than ordinary persons (Douglas 2011a).

Finally, a third response to concerns regarding the creation of SEBs has been to argue that, even if human neuroenhancements could create SEBs *and* this would be bad for ordinary persons, it may still be morally permissible, or even morally desirable, to create such beings. For example, Douglas (2011a, 2012), Persson (2012) and Wasserman (2012) argue that the costs to ordinary persons associated with the existence of SEBs might be compensated by other advantages or might be outweighed by goods enjoyed by the SEBs themselves. By contrast, Agar (2012a) has argued that the costs of MSNs for the unenhanced are unlikely to be compensated by other benefits.

Moral Desirability Neuroenhancements

Moral desirability enhancements (MDNs) aim to augment and (expectably) succeed in augmenting the moral desirability of a person's character traits, motives, or conduct (henceforth, collectively, "psychological features"). The moral desirability

[1]Each of these authors relies to some extent on an inductive inference, most fully spelled out by Agar (2012a): observed differences in mental capacity generate differences in moral status, and unobserved differences in mental capacity, between us and mentally enhanced beings, could be at least as great; thus we should expect that these too will give rise to differences in moral status. David Wasserman (2012) has recently offered an inductive argument militating in the opposite direction. He notes that the development of civilization, for example, from feudalism to contemporary social arrangements, has tended to elide distinctions in moral status so that we now accept fewer tiers of moral status than previously. If we assume that this is due to moral-epistemic progress, then we might infer that we are in the process of converging on a correct view of moral status that accepts very few tiers of moral status (perhaps simply a binary view that entities either have moral status or not). Such a view might render implausible the claim that mentally enhanced beings could have greater moral status than us.

of a psychological feature – often referred to simply as its moral goodness – corresponds to, or is at least correlated with, the degree to which there are typically agent-neutral moral reasons to promote that feature. It is to be distinguished from the moral worth or *moral praiseworthiness* of a psychological feature (also sometimes referred to using the term "moral goodness") which is instead standardly understood as the degree to which an agent merits moral praise for possessing that feature. Morally desirable traits are often also morally worthy, but they need not be.

Some psychological features may be *noninstrumentally* morally desirable. For example, Kant (1964) can be interpreted as arguing that a good will is noninstrumentally morally desirable, many have held that those character traits which qualify as virtues are noninstrumentally morally desirable, and many would also hold that respectful actions are, at least in one respect, noninstrumentally morally desirable. But character traits, motives, and actions can also be *instrumentally* morally desirable, because they produce outcomes that are themselves morally desirable. For example, breaking a promise, might be in one way instrumentally morally desirable when it results in lives being saved, pain being averted, or knowledge being gained. In what follows, moral desirability will be taken to include both instrumental and noninstrumental moral desirability. MDNs can thus be understood as interventions aim to increase and (expectably) succeed in increasing the total instrumental and noninstrumental value of a person's character traits, motives, or conduct.

Note that, on some views, the same interventions will qualify as both moral status neuroenhancements and moral desirability neuroenhancements. For example, on some Kantian views, possession of a good will is both a morally desirable character trait and what confers moral status on a being. Some such views might allow that improving a person's will via neuroenhancement – supposing that this were possible – could constitute both a MSN and a MDN.

Types of Moral Desirability Neuroenhancement

MDNs are unified by the kind of moral value that they augment: moral desirability. However, as already noted, they may differ in their target, with some targeting a person's conduct, others her motives, and others still her character traits. MDNs that target a person's character or character traits could be aptly described as enhancements of moral virtue since, on some accounts of virtue, the moral virtues are understood to be morally desirable character traits. However, moral virtue is also sometimes understood in other ways – for example, as referring to morally *praiseworthy* character traits.

MDNs can also be distinguished by the means they employ. As instances of neuroenhancement, all MDNs operate by directly modulating the brain states of an agent. However, we can distinguish them according to the way in which brain modulation is supposed to enhance the moral desirability of the agent's character,

motives, or conduct. Some MDNs might operate by directly altering an agent's mental *capacities or abilities* but without directly influencing any mental state. For example, Fröding (2011) suggests that certain cognitive neuroenhancements, such as those which mitigate cognitive biases, would in some cases facilitate the development of moral virtues. Similarly, one can imagine that an intervention which enhanced an agent's ability to vividly imagine the consequences of her actions might contribute to morally more desirable conduct.

These interventions would alter mental states only indirectly, by influencing the agent's mental capacities. Other MDNs might operate by directly influencing an agent's mental states, for example, by directly altering the agent's beliefs, desires, intentions, or emotions. Perhaps an intervention could enhance the moral desirability of an agent's conduct by augmenting her feelings of sympathy, her desire to help others, or her belief in the importance of moral requirements. Within the category of MDNs that directly influence an agent's mental states, we can distinguish between those that directly influence cognitive states (such as beliefs), conative states (such as desires and intentions), and affective states (such as emotions). As discussed below, some concerns that have been raised about MDNs are specific to MDNs that operate by directly altering mental states of certain kinds.

Scientific Prospects for Moral Desirability Neuroenhancement

Spence (2008) argues that, within psychiatry, some medications, such as those used to treat antisocial personality disorder, substance abuse, and psychosis, are already being used as MDNs in some circumstances. It might also plausibly be argued that anti-testosterone agents and other medications used to prevent sexual re-offending in some European and North American jurisdictions are intended to improve the moral desirability of the sex offender's conduct.

Most discussions of MDNs have, however, treated such enhancements as a prospect for the future rather than a contemporary phenomenon. To establish the plausibility of the claim that MDNs might become feasible or commonplace in the future, some have pointed to recent findings from moral psychology and neuroscience which are beginning to uncover the neural bases of morally significant character traits, motives, and behavior and, in some cases, to suggest possible interventions capable of modifying these (e.g., Savulescu and Persson 2012). For example, the neurotransmitter oxytocin appears to have significant affects on trust and cooperativeness between people (e.g., De Dreu et al. 2010, 2011; Kosfeld et al. 2005; Zak et al. 2004), and a number of widely used drugs, including the beta-blocker propranolol and selective serotonin reuptake inhibitors, a class of antidepressants, appear to have significant effects on human moral psychology (e.g., Crockett et al. 2008, 2010; Terbeck et al. 2012). Shook (2012) and Levy et al. (forthcoming) review some recent empirical findings relevant to future prospects for developing new MDNs.

Motives for Discussing the Morality of Moral Desirability Neuroenhancements

There have been two main motives for assessing the morality of MDNs. Some have assessed hypothetical MDNs as a way to test arguments that have been made regarding the morality of neuroenhancement or bioenhancement more generally (section introduction in ► Chap. 75, "Neuroenhancement" and ► Chap. 80, "Reflections on Neuroenhancement," ► Chap. 69, "Using Neuropharmaceuticals for Cognitive Enhancement: Policy and Regulatory Issues" ► Chap. 76, "Ethics of Pharmacological Mood Enhancement"). For example, Douglas (2008) presents certain MDNs as counterexamples to the claim that it is always morally impermissible to biologically augment one's capacities from an already normal level.

Other authors have discussed MDNs for more practical reasons: because they believe that there is a realistic prospect of MDNs being attempted in the future and wish to encourage, forestall or morally appraise such attempts or the technological developments that would enable them. For example, Ingmar Persson and Julian Savulescu have argued that MDNs might help humanity to escape its own destruction and should therefore be pursued, while John Harris, Robert Sparrow, Nick Agar, and others have raised serious moral concerns regarding MDNs.

The following two sections outline some of the main moral positions that have been taken on MDNs and the dominant arguments that have been made for and against those positions. As in the discussion of MSNs, arguments concerning the *possibility* of MDNs are discussed only insofar as they have figured in arguments concerning their morality.

Persson and Savulescu's Defense of an Imperative to Pursue the Development of MDNs

The most forthright and provocative defense of MDNs has been offered by Ingmar Persson and Julian Savulescu, who argue that there is "an urgent imperative to enhance the moral character of humanity" and to pursue research into moral neuroenhancements as a possible means to this end (2008, p. 162; see also 2010, 2011a, b, 2012). Persson and Savulescu argue that scientific progress, aided by cognitive neuroenhancement, is likely to bring it about that even small numbers of malevolent agents could cause great harm. For example, they suggest that scientific advances may allow a single scientifically trained individual to produce a designer pathogen capable of wiping out humanity, making it almost certain that humanity will indeed be destroyed. On the other hand, they argue, scientific progress will not have any benefits sufficiently great to make it rational to accept this risk of great harm, in part because it is generally easier to cause a harm than to cause a comparably large benefit and in part because it is rational to be somewhat more averse to harms than attracted to benefits. They maintain that:

> It will be bad for us that scientific knowledge continues to grow by traditional means, and even worse if this growth is further accelerated by biomedical or genetic enhancement of our cognitive capacities. For if an increasing percentage of us acquires the power to destroy a large number of us, it is enough if very few of us are malevolent or vicious enough to use this power for all of us to run an unacceptable increase of the risk of death and disaster. To eliminate this risk, cognitive enhancement would have to be accompanied by a moral enhancement which extends to all of us, since such moral enhancement could reduce malevolence. (2008, p. 166)

This moral enhancement, as they understand it, will consist in the acquisition of morally better (in the sense of more morally desirable) motivational dispositions. Persson and Savulescu argue that neither traditional forms of moral enhancement, such as moral education, nor cognitive enhancements (traditional or otherwise) are likely to produce the necessary moral enhancement. They also suggest that it is unlikely that the risks of great harm can be mitigated by holding back cognitive enhancement and scientific progress (2008, p. 173). They argue that we should thus pursue the possibility of moral neuroenhancements by, among other things, conducting scientific research that might facilitate their development (on this claim, see also Hughes 2006, 2011). This argument has attracted four main types of criticism.

Criticism 1: Misconstrual of the Risks and Benefits of Scientific Progress

One critical response has been to argue that Persson and Savulescu have overstated the risks or understated the benefits associated with further scientific progress. For example, Elizabeth Fenton maintains that, in characterizing the likely benefits of scientific progress as consisting in "only a *small* increase in an *already high* quality of life," Persson and Savulescu both underestimate the size of the likely benefits of scientific progress and misconstrue the likely starting point (2010, p. 149, her italics). She argues that the benefits of scientific progress would in many cases be enjoyed by individuals whose quality of life is poor, for example, due to disease, famine, or pollution, and for whom the benefits of such progress would be substantial. She also argues, appealing to Buchanan (2008), that further scientific progress might in fact be necessary to prevent significant decreases in quality of life (p. 150).

John Harris (2011) also offers a response of this second variety. He disputes Persson and Savulescu's claim that it is generally easier to harm than to benefit others by appealing to cases in which it seems easy to cause large benefits by making donations, initiating public health programs, providing vaccines, or preventing others from inflicting great harm (pp. 106–107). Suppose you know that someone is planning a mass shooting and have access to the gun they will use; you might then be able to save many lives by removing the bullets from this gun. Harris suggests that in this sort of case it is at least as easy for you to save the lives at stake as it is for the prospective shooter to end them.

Harris has also argued that cognitive neuroenhancement is itself a variety of moral neuroenhancement (2011, e.g., pp. 106, 110). The implication is that if future

technological progress is driven in part by cognitive neuroenhancement, we can expect that future people will also have more morally desirable character traits, motives, and conduct than us. This might somewhat mitigate the risk that new technologies will be used to harmful effect.

Persson and Savulescu offer a number of replies to claims that they have misconstrued the risk-benefit balance associated with further technological development, but perhaps the most important of these involves an appeal to the concept of ultimate harm: this is the harm of bringing it about that worthwhile life will never again exist. Persson and Savulescu argue that scientific progress will increase the risk of ultimate harm, and they take this to be an indefinitely bad outcome since, we have no way of knowing how much net value, in the form of continued worthwhile life, the ultimate harm prevents (e.g., 2011a, p. 442). On the other hand, they doubt that technological progress will similarly increase the likelihood of indefinitely good benefits.[2] Thus, they claim, we are in the position of weighing indefinitely bad harms against substantial but definite benefits, and faced with this choice it is rational to prefer that there is no further technological progress.

Criticism 2: Misuse of Moral Enhancement Technologies

Persson and Savulescu are concerned that the products of technological development might be misused to devastating effect. Some authors have responded by noting that the moral enhancement technologies whose development they call for, or the scientific information that would need to be acquired in order to develop them, could themselves be misused by malevolent agents (Ehni and Aurenque p. 231–2; Fenton 2010; Harris 2011, p. 108; Sparrow forthcoming a, b). Presumably, if we were technologically capable of bringing it about that people have *more* morally desirable character traits, motives, or conduct, we could also bring it about that people have *less* desirable traits, motives, or conduct, and some agents might well be more interested in decreasing moral desirability than increasing it. For example, we can imagine that a ruthless businessman or soldier might want to suppress pangs of conscience and that this might bring about morally undesirable motives and conduct.

Persson and Savulescu's response to these concerns has been to concede that technologies which enable MDNs could be misused but maintain that pursuit of MDNs is nevertheless our only hope of avoiding ultimate harm (Persson and Savulescu 2011a, p. 443).

[2]Persson and Savulescu (2011b, p. 4) do allow that one might contribute to an indefinitely large benefit by preventing someone else from causing ultimate harm, something that technological progress might allow. However, they argue that, in that sort of case, one would not be *guaranteeing* an indefinitely large benefit, because someone else (or a natural disaster) might cause ultimate harm. By contrast, when one causes ultimate harm, one does guarantee an indefinitely bad harm.

Criticism 3: Implausible Implications

Persson and Savulescu have also been criticized for being committed to intuitively implausible views. For example, Fenton (2010) argues that they are committed to the view that "*all* forms of scientific progress are instrumentally bad for humans overall" (p. 149, her italics). Their response is to argue that there has been a turning point. Before that point, scientific progress could be expected to produce net benefits; afterwards, it could be expected to produce net harms. They suggest that this turning point occurred when "science and technology put in the hands of humans the means of destroying or seriously damaging forever the conditions of sentient life on this planet" and speculate that this point may have come in the mid-twentieth century (Persson and Savulescu 2011a, p. 441). Meanwhile, Harris (2011) argues that Persson and Savulescu are committed to the view that it would be in one way desirable to retard the cognitive powers of current and future humans, thus slowing scientific progress.

Criticism 4: Moral Neuroenhancement Won't Help

A fourth criticism of Persson and Savulescu's argument maintains that pursuit of moral enhancement would do little to diminish the risk of ultimate harm (Harris 2011, pp. 109–10). Since the risks that worry Persson and Savulescu are risks that could be created by lone malevolent agents, and since those agents are also likely to be able to avoid undergoing moral enhancement, it may seem doubtful whether pursuit of moral enhancement would do much to reduce these risks.

In response, Persson and Savulescu (2012) argue that technological progress can exacerbate risks of ultimate harm not only by allowing lone agents to wreak great havoc but also by exacerbating the negative effects of widespread but mundane moral failings. For example, they argue that climate change may cause ultimate harm and that it can be attributed to a combination of technological development and human moral failings. Moral neuroenhancement might be capable of substantially reducing climate change even if not universally undergone. Thus, they suggest, MDNs might reduce some risks of ultimate harm even if they would fail to reduce others.

Other Defenses of MDNs

Persson and Savulescu are interested in whether humanity falls under an imperative to pursue or promote the development of technologies that would enable MDNs. However, there are many other moral questions that we might ask regarding the morality of MDNs. For example, we might ask whether there is some weaker moral conclusion that could be made in favor of pursuing the development of MDNs: even if humanity falls under no imperative to promote MDNs, it might nevertheless be morally permissible, or even morally desirable, for it to do so. We could also

move away from questions about what humanity as a whole ought to do to questions about what individual people, or groups of people, ought to do. Again, even if humanity falls under no imperative to promote MDNs, it might nevertheless be permissible, desirable, or obligatory for individual people or groups of people to promote MDNs, to undergo MDNs themselves, or to encourage or require others to do so.

There is thus scope for weaker defenses of MDN, and a number of such defenses have been offered. For example, Thomas Douglas (2008) has argued that it would often be morally permissible for individuals to voluntarily engage in MDNs that expectably bring it about that they have more morally desirable motives than they would otherwise have had. More recently, David DeGrazia (2012b) has argued that moral desirability enhancements of motives or behavior would themselves be morally desirable, under certain idealizing assumptions. There have also been weaker defenses of specific means to MDN. For example, Douglas (2011b) argues that it could be morally permissible to enhance the moral desirability of one's motives or conduct via *directly modulating one's emotions* – that is, via means which, once set in train, modulate one's emotions without requiring the engagement of one's deliberative capacities.

It would be relatively uncontroversial that individuals have moral reasons to enhance the moral desirability of their character, motives, and conduct, and that doing so is in one way morally desirable. These may even be analytic truths. Moreover, MDNs appear to be immune to many of the general concerns that have been raised about neuroenhancements (or bioenhancements more generally). These concerns have often focused on ways in which neuroenhancements undergone by some individuals might harm or wrong others, for example, by placing them at an unfair competitive disadvantage or undermining commitments to solidarity or equality. MDNs are unusual among the main types of neuroenhancements that have been discussed heavily in recent literature in that they might plausibly be expected to advantage, rather than disadvantage, others, on balance.

Nevertheless, some significant concerns have been raised regarding the permissibility and desirability of undergoing MDNs or certain kinds of MDNs. Some of these are general concerns about enhancing the moral desirability of our characters, motives, and conduct, whether through *neuro*enhancement or more traditional means. In this category are general skepticism about the possibility of moral improvement and concerns about whether we have adequate means of resolving disagreement and uncertainty about what character traits, motives, and conduct are morally desirable and why. Debate regarding MDNs has elicited significant moral discussion on these points (Jotterand 2011; Schaefer 2011; Shook 2012; Wasserman 2011), but these concerns apply to traditional means of augmenting moral desirability as well as MDNs. Other concerns are general concerns about neuroenhancement that would apply to nonmoral neuroenhancements as much as to MDNs. In this category are concerns regarding the unnatural means or hubristic motives that neuroenhancement is said to involve (Kass 2003; Sandel 2007). Other concerns are, however, specific to MDNs – they would not apply equally to traditional means of enhancing moral desirability or to other kinds of

neuroenhancement. The remainder of this section outlines three dominant concerns in this category as well as some responses that have been offered to them by those who wish to defend at least some MDNs.

Concern 1: Restriction of Freedom

One concern that has been raised regarding MDNs, or certain MDNs, is that such enhancements might restrict freedom or autonomy. Thus, for example, John Harris (2011) argues that we might have reason to abstain from MDNs because they would restrict our freedom to perform morally undesirable actions or to have morally undesirable motives (see also Ehni and Aurenque 2012, p. 233 and, for a more general discussion of the effects of neuroenhancement on autonomy, Bublitz and Merkel 2009).

A similar thought underpins the well-known free will defense of theism. The free will defense maintains that the existence of an omnipotent, omniscient, and benevolent God is consistent with the presence of evil because evil is a consequence of our possessing the freedom to do evil, which is, all things considered, good. Though the freedom to do evil possesses the instrumental disvalue of allowing evildoing, it also possesses some other, greater value. It is no surprise, then, that an omnipotent, omniscient, and benevolent God would have allowed evil to exist.

If the freedom to do evil is all-things-considered valuable despite its very great instrumental disvalue, one might expect that the more general freedom to have morally undesirable character traits or motives or to act in morally undesirable ways (henceforth, the freedom to be immoral) is also good despite its instrumental disvalue. Perhaps, then, MDNs will be all-things-considered disvaluable whenever they restrict this freedom.

Two main types of response have been made to this suggestion. The first has been to argue that, even where MDNs do restrict freedom, it might nevertheless be morally permissible or all-things-considered morally desirable to undergo such MDNs. The second has been to deny that all MDNs would restrict freedom, thus limiting the concern about freedom to a subset of MDNs.

Responses of the first type parallel a standard response to the free will defense of theism. That response holds that, in many cases, it seems preferable to sacrifice some freedom to do evil in order to prevent evil than to tolerate both the freedom to do evil and the associated evil. If I witness one person about to murder another, it seems that I should intervene to prevent the murder even though this involves restricting the prospective murder's freedom to do evil. Similarly, it seems that a would-be murderer should restrict his own freedom to do evil, thus preventing murder, if he is in a position to do so. The obvious way of explaining this conclusion is to suppose that, in at least some cases, any disvalue associated with restricting one's freedom to do evil is outweighed by the value of doing so. Similarly, it has been argued that there will be MDNs where the disvalue of any loss in freedom to be immoral is outweighed by the

value of increasing the moral desirability of one's motives or conduct (DeGrazia 2012b; Douglas 2008, 2011b; Savulescu et al. forthcoming; Savulescu and Persson 2012).

Responses in the second category sometimes begin by noting that concerns about the freedom-reducing effect of MDNs presuppose compatibilism – namely, the view that freedom is consistent with one's motives and conduct being causally determined. For if compatibilism were false, we could be free only if we were causally undetermined. In that case, we would either already be completely unfree, because we are causally determined, in which case MDNs could not *reduce* our freedom, or we are free only because we are, at least some of the time, immune from causal forces, in which case MDNs, which operate through causal channels, could not affect us in circumstances where we are currently free (Blackford 2010; DeGrazia 2012b; Savulescu et al. forthcoming; Savulescu and Persson 2012).

Thus, it is argued, concerns about the freedom-reducing effect of MDNs will have to be grounded on compatibilism. But on compatibilist views of freedom, whether MDNs diminish freedom is likely to depend on precisely how they operate.

We can think of compatibilists as distinguishing between two aspects of our psychological life: a true or authentic self (which may be identified with higher order desires, or higher order desires that are not the result of inauthentic influences) and a brute self. Motives or actions are then thought of as free if and only if they are part of or flow from the true self.

On this picture, MDNs could reduce our freedom to be immoral if they operate by strengthening the influence of the brute self vis-à-vis the true self. Consider an individual who, whenever approached by poverty-relief charities, feels a conflict between, on the one hand, a firm commitment, formed through introspective reflection, to the view that she owes nothing to the poor, and on the other hand, feelings of sympathy towards the poor which are the result of extraneous social pressures and which she experiences as unwanted. Suppose further that this individual, under social pressure, undergoes an intervention that directly augments her feelings of sympathy. Such an intervention might perhaps qualify as a MDN, and it will also, on many compatibilist views, restrict her freedom. A proponent of these views would deem this agent's feelings of sympathy, both before and after the intervention, to be aspects of her brute self, while her moral commitments regarding charity are an aspect of her true self. The intervention might thus plausibly be construed as one in which the influence of the agent's brute self is expanded at the expense of the agent's true self. One might expect that, following the intervention, a greater proportion of this agent's motives and conduct would be unfree, where that implies that they are part of or flow from the brute, rather than the true, self.

However, defenders of MDNs have argued that, just as we can paint a compatibilist picture of a MDN that restricts the freedom to be immoral, so too we can paint a picture of one that operates by increasing the freedom to be moral. They argue that, on any plausible compatibilist account of freedom, there will be some ways in which the conduct of some people is already unfree – because it flows from aspects of our brute selves. MDNs could operate precisely by attenuating the

influence of these aspects of our brute selves (Douglas 2008, 2011b; Savulescu et al. forthcoming). Thus, suppose that, when an agent is approached by worthy poverty-relief charities, she feels a pull between a reflectively formed commitment to the view that poverty-relief is morally required and a hoarding instinct not to part with any of one's property that is unwanted and the result of external factors. In this case, many compatibilist views will deem the moral commitment to be part of the true self and the hoarding instinct to be part of the brute self. Thus, it will be plausible that an MDN that attenuated the hoarding instinct would increase the agent's freedom.

Concern 2: Superficiality

A second concern that has been raised regarding MDNs is targeted specifically at Douglas' defense of MDNs that increase the moral desirability of one's motives or conduct by directly modulating emotions (call such interventions "Emotional MDNs"). John Harris worries that an intervention which operates in this way "cannot be moral enhancement properly so called at all". Indeed, he maintains that "the notion of moral behaviour has been attenuated to a vanishing point" once one claims that such behavior could be produced by directly altering emotions (2012a, p. 6); "tinkering with the emotions is not a form of moral enhancement at all. It is more like the threat of punishment: it may make immoral behaviour less likely, but it does not enhance morality" (2012b, pp. 3–4; see also Harris and Chan 2010; Sparrow forthcoming a, b).

One way of reading these passages would see them as asserting that Emotional MDNs are metaphysically, or at least physically, impossible. They violate some metaphysical or physical law. (Doubts regarding the possibility of MDNs more generally have also been raised by Ehni and Aurenque 2012, p. 232; Jotterand 2011; and Shook 2012.) However, it is difficult to see how this charge could be sustained. Emotions are mental states; mental states are normally taken to be either constitutively or causally dependent on brain states, and brain states are susceptible to direct modulation. It seems both metaphysically and physically possible to alter the emotions by directly influencing brain states. It also seems metaphysically and physically possible for alterations in one's emotions to alter the moral desirability of one's motives or conduct. For example, gratuitous killing of innocents in war is morally undesirable, and it is plausible that differences in the extent to which a solider experiences emotions such as an uncontrollable rage might influence whether or not that soldier engages in such morally undesirable conduct.

Perhaps a more plausible way of interpreting Harris' passages would see them as conceding that direct modulation of emotions could increase the moral desirability of one's motives or conduct but maintaining that it could not produce some deeper kind of moral improvement for which the term "moral enhancement" should be reserved. Fabrice Jotterand (2011) makes a similar point, arguing that "moral neuroenhancement is unlikely to morally enhance people in the true meaning of the word" (p. 8), as does Robert Sparrow (forthcoming b), who suggests that

"while there is indeed evidence that certain pharmaceutical and neuro-scientific interventions can alter dispositions and behaviour in ways that we may be inclined to morally evaluate positively, this falls well short of constituting 'moral bioenhancement' in any interesting sense." These authors might be read as suggesting that the direct modulation of emotions could not produce *deep* moral improvement, where that might consist, for example, in an increase in the moral *worth* or *virtue* of one's motives or conduct.

It would not, of course, follow from this that Emotional MDNs are absolutely morally undesirable in any way. To claim that Emotional MDNs fail to produce deep moral improvement is to claim that they lack some desirable feature, not that they possess some absolutely undesirable one. However, if Emotional MDNs fail to produce deep moral improvement, it might follow that they are *less* morally desirable than certain other ways of enhancing the moral desirability of our conduct that do produce deep moral improvement. Harris (2011, 2012a, b) can be read as maintaining that, while Emotional MDNs fail to produce deep moral improvement, more traditional, deliberative means of enhancing moral desirability, such as introspective reflection and engagement with literature, do produce such improvement and should thus generally be adopted in preference to MDNs.

Harris buttresses his claim that Emotional MDNs could not produce deep moral improvement by drawing a parallel between "being moral," in the deeper sense in which he is interested, and "being scientific":

> [o]ne can accidentally discover something of scientific importance, but one cannot be scientific, one cannot do science, accidentally. Doing science is a deliberative and disciplined process. It involves, for example, doing things like formulating and testing a hypothesis and looking for disconfirmatory evidence as well as for confirmatory evidence. . .Being moral is like being scientific. (Harris 2012a, p. 6)

He suggests that, unlike traditional means of enhancing moral desirability, Emotional MDNs could bring about morally desirable motives and conduct only by accident. One might ground an argument for this view on the observation that traditional means of enhancing moral desirability frequently operate by enhancing an agent's moral understanding: her understanding of what morality requires and why, both in general and on particular occasions on which one must make a morally significant decision. This moral understanding is an all-purpose tool that helps the agent to be motivated and act in morally desirable ways in many circumstances. If an agent understands what morality requires and why, she will be well placed to be motivated and act in morally desirable ways in almost any circumstance.

On the other hand, Harris (2012a, b) suggests, Emotional MDNs would not operate by enhancing the agent's moral understanding. Others have made similar claims. For example, Fabrice Jotterand (2011) argues that "[w]hile the manipulation of moral emotions might change the behavior of an individual, it does not provide any content, for example, norms or values to guide one's behavioral response" (p. 6, see also p. 8). Similarly, Robert Sparrow (forthcoming a) suggests that "[i]t is hard to see how any drug could alter our beliefs in such a way as to track the reasons we have to act morally" and that "[s]omeone who reads Tolstoy arguably learns to be less

judgemental and in doing so develops greater understanding: someone who takes a pill has merely caused their sentiments to alter." If these authors are correct, Emotional MDNs (and perhaps MDNs more generally) do not augment moral understanding. Instead, it might be argued, Emotional MDNs would typically work by removing some relatively straightforward emotional barrier to morally desirable motivation or conduct. The most obvious examples of such obstacles might include aggressive impulses, strongly xenophobic sentiments, or a callousness or ruthlessness towards the suffering of others. But note that these are not *universal* barriers to moral desirable motivation and conduct. For example, one can imagine circumstances in which aggressive impulses or ruthlessness would produce morally desirable motives and conduct; aggressiveness might do so when one is fighting a just war, or perhaps when one is confronted with one person assaulting another on the street, and ruthlessness might do so when one is a politician engaged in diplomatic negotiations (Douglas 2008; Savulescu et al. forthcoming; Wasserman 2011, forthcoming). Thus, it might be thought that Emotional MDNs would produce only accidental or unreliable morally desirable motives and conduct.

There is little literature responding to Harris' concern about the superficiality of Emotional MDNs nor to the suggestion that Emotional MDNs could produce no more than accidental morally desirable motives and conduct. However, some defenders of MDN have suggested that such neuroenhancements could operate by attenuating emotional barriers to sound moral deliberation (Douglas 2008, forthcoming) or by bringing it about that we are more like those existing people who we regard as especially moral (Savulescu and Persson 2012; Savulescu et al. forthcoming), and one might expect that where they operate in this way they will, like more traditional forms of moral enhancement, increase moral understanding. In addition, Wasserman (2011) has argued that, even if an Emotional MDN initially had no positive effect on moral understanding, we might expect the frequent presence of pro-moral emotions and the morally desirable motives or conduct to lead to a development in moral understanding over time. This parallels the Aristotelian point that one comes to know the good by being good (Burnyeat 1980).

Concern 3: Misfiring

A third concern that can be raised regarding MDNs maintains that attempts at MDNs are likely to misfire, bringing about moral deteriorations rather than improvements. This is not a concern about successful MDNs but is rather the concern that actual attempts at MDN are likely to be unsuccessful.

Harris (2011) advances this concern by noting that "the sorts of traits or dispositions that seem to lead to wickedness or immorality are also the very same ones required not only for virtue but for any sort of moral life at all" (p. 104). He infers from this that the sorts of psychological alterations required for MDN would involve not the wholesale elimination or dramatic amplification of particular dispositions, but rather a kind of fine-tuning of our dispositions (see also Jotterand 2011, p. 7; Wasserman 2011). However, he argues that the disposition-modifying neurotechnologies that we are

actually likely to have available to us will be rather blunt: it will be difficult to determine or even predict their effects precisely or to target the specific dispositions that we wish to shape. Thus, he suggests, it is unlikely that any attempt to use these technologies will succeed in bringing about an improvement in the moral desirability of our motives or conduct.

Nicholas Agar (2010, 2012b, under review) puts forward a more limited variant of this concern. He argues that attempted MDNs may have good chances of success when they aim only to correct subnormal levels of moral desirability, bringing an individual within the normal range, but that they are likely to misfire when they aim to produce levels of moral desirability above the normal range. Subnormal moral desirability is often the result of relatively isolated and easily identified defects such as, for example, the deficient empathy that characterizes psychopathy. Agar speculates that these defects could relatively safely be corrected. However, he argues that, to attain supranormal levels of moral desirability, we would need to simultaneously augment or attenuate several different dispositions in a balanced way. This, he claims, will be very difficult. One might suppose that this difficulty derives from three sources. First, there may be moral uncertainty – uncertainty regarding what character traits, motives, or conduct qualify as supranormally morally desirable. There would be significant disagreement on this matter and that this disagreement may be both evidence for and a source of uncertainty (see, e.g., Schaefer 2011). Second, there may be empirical uncertainty about what changes would need to be wrought in a given individual to realize the putatively desirable traits. Third, there might, for reasons suggested by Harris (2011), be practical difficulties in realizing these transformations using technologies that we have available to us. Taken together, these difficulties might create a serious risk that attempts to bring about supranormal MDNs will fail.

The main response made to these concerns by defenders of MDN has been concessive. Defenders of MDNs have acknowledged both that (1) in many cases, complex and subtle interventions would be needed in order to enhance moral desirability and that (2) this creates a risk that attempted MDNs will fail, perhaps instead resulting in moral deterioration (Douglas 2011b; Savulescu et al. forthcoming). However, some doubt has been cast on the thought that this concern would always count decisively against attempting MDNs. For example, Douglas (2011b) notes that there are other areas – such as clinical psychiatry – where we often also use rather blunt biological interventions as part of efforts to achieve subtle and multidimensional psychological changes. Yet in that area we normally think that attempting some interventions can be permissible and desirable if undergone cautiously, keeping open the option of reversing the intervention if it misfires. He suggests a similar approach might be justified in relation to MDNs.

Further Questions

Moral debate on MDNs has focused primarily on (1) the morality of promoting the development of technologies that would enable MDNs, as in the case of discussion

surrounding Persson and Savulescu's proposals, and on (2) the morality of voluntarily undergoing MDNs oneself, as in the case of discussion surrounding Douglas' and DeGrazia's proposals. Further questions might be asked regarding the morality of requiring or encouraging others to undergo such neuroenhancements. For example, one might wonder whether it would ever be permissible for a state to impose MDNs on its citizens, for courts to impose MDNs on convicted offenders, for parents to impose MDNs on their children, or for employers to impose MDNs on their employees. Such uses of MDNs would raise, in addition to the concerns discussed above, concerns regarding, inter alia, coercion, manipulation, and domination. For example, Sparrow suggests that imposing moral enhancements on others might, even if benevolently motivated, constitute an objectionable form of domination (forthcoming; under review; see also Bublitz and Merkel 2009). Walker (2009) and Blackford (2010) have responded to similar concerns as they might be raised in relation to the imposition of MDNs on one's children or children-to-be.

Perhaps the context in which coercive use of MDNs is most likely to gain acceptance is that of criminal justice. Arguably, institutions of criminal justice are, at least insofar as they offer criminal rehabilitation programs, already engaged in a kind of moral enhancement. In addition, concerns about moral disagreement might be regarded as least serious in this context; criminal conduct is conduct that, if not universally taken to be morally undesirable, is at least widely accepted as conduct which the state and citizenry may legitimately seek to prevent. Concerns regarding coercion might also be regarded as weaker in the context of criminal justice, since a degree of coercion is also already accepted in that area: the paradigmatic criminal sanction, incarceration, is itself highly coercive. Nevertheless, it might be argued that forced MDNs in criminal justice would be more problematic than either incarceration or psychological rehabilitation programs, perhaps because more intrusive or manipulative. There is a burgeoning literature on this topic (Bomann-Larsen 2011; Bublitz and Merkel 2012; Rosati 1994; Ryberg and Petersen 2011; Shaw 2012; Vincent 2012).

Questions might also be asked regarding the morality of selecting for morally desirable character traits in one's children, for example, on the basis of genetic information acquired through preimplantation genetic diagnosis. Moral enhancement and moral neuroenhancement have been understood in this chapter to involve augmenting the morality of some particular individual or her traits. On this understanding, selecting for moral traits in one's children would not qualify as moral neuroenhancement, or indeed moral enhancement, since it instead involves bringing one (expectably) more moral individual into existence in preference to another (expectably) less moral individual. However, some of the same issues arise in cases of selection as in cases of neuroenhancement discussed here, and there is some literature exploring these. For example, Faust (2008) argues that if parents were able to select for morally desirable traits in their future children, it would be desirable, and probably obligatory, for them to do so. Walker (2009) argues that there is no principled reason not to select for moral virtues in one's children, unless there is a principled reason not to engage in

selection at all.[3] For criticism of these claims, see Agar (2010), Andreadis (2010), Arnhart (2010), and Bronstein (2010).

Reflections on Neuroenhancement

Contents

Abstract

Neuroenhancement through psychopharmacology can improve a range of cognitive and affective functions involved in practical and moral reasoning and decision-making. In this chapter, the claim that this type of enhancement would adversely alter human nature will be examined, and it will be argued that the claim is unfounded because it is based on questionable assumptions. In addition, some of the neurobiological risks associated with cognition-enhancing drugs will be considered. It will be pointed out that answers to questions about risk can only be provided after a sufficient number of prospective controlled studies of the drugs' effects have been conducted. On the basis of studies conducted thus far, less pronounced effects of these drugs on the cognitively better off and more pronounced effects on the cognitively worse off suggest that they would not increase and might decrease social inequality. Finally, empirical evidence for the potential of drugs to enhance moral sensitivity and moral motivation will be considered and some of the social implications of the effects of the drugs will be explored. If the drugs were effective in making us more responsive to moral reasons for and against

beneficial and harmful actions and promoted moral progress, there would remain the question of how to balance the collective interest against individuals' right to choose not to enhance.

Introduction

Neuroenhancement is the improvement of brain and associated mental functions beyond what is considered normal for the general population (Juengst 1998). It includes improving such cognitive capacities as information processing, concentration, and practical decision-making. It also includes improving the cognitive and affective capacities necessary for moral reasoning about actions that benefit or harm others. While there has been speculation on the possibility of enhancing neural and mental functions through genetic modification, this type of intervention is still unproven. In contrast, many people have enhanced mental functions through psychopharmacology for generations, and this practice is becoming more pervasive especially among adolescent and young adult populations. Some studies estimate that approximately 25 % of American secondary school students use psychostimulants such as dextroamphetamine (Adderall), methylphenidate (Ritalin), and the wakefulness-promoting drug modafinil (Provigil) for the nontherapeutic purposes just mentioned (Wilens et al. 2008; Greely et al 2008). Earlier studies estimated that roughly 7 % of US university students used these drugs for the same purposes (McCabe et al 2005). Roughly 5 % of the working population in Germany uses psychotropic drugs to enhance their cognitive functions (Heinz et al. 2012). In 2008, the journal *Nature* published the results of an informal survey of its readers (Maher 2008; Sahakian and Morein-Zamir 2007). One-third of the 1,400 readers who responded said that they had used these drugs for off-label nontherapeutic reasons. The use of these drugs to perform better on exams, write more successful grant applications, or improve work performance is likely to increase.

Some opponents of neuroenhancement claim that it will alter and adversely affect our human nature (Kass 2003; Sandel 2007). Others point out that the risks of chronic use of psychotropic drugs to improve mental functions may outweigh the benefits (Heinz et al. 2012). Still others claim that enhancement will increase social inequality and injustice (Habermas 2003). Proponents argue that human nature is not fixed but evolving and has many imperfections that provide compelling reasons for using drugs to improve our capacity for practical and moral reasoning (Harris 2007). They argue that cognitive enhancement will not necessarily result in a zero-sum world of increased competition but instead will increase productivity and result in significant benefits for both individuals and society (Buchanan 2011a, b). Moreover, they argue that enhancing our limited moral capacities will be especially beneficial because it will promote pro-social behavior and reduce the harm resulting from self-interested behavior. Moral enhancement could help to defuse two particularly pressing threats to the survival of human and nonhuman species: the potential use of weapons of mass destruction and environmental degradation (Persson and Savulescu 2011, 2012).

This chapter will first address the claim that neuroenhancement will have a negative impact on human nature. It will be shown that this claim is largely unfounded and rests on questionable assumptions without adequate supporting arguments. The chapter will then consider the risk of addiction from chronic use of cognition-enhancing drugs. A definitive answer to the question of whether this risk is significant enough to limit or prohibit their use will not be available until a sufficient number of long-term controlled studies of the drugs' effects have been conducted. Based on evidence from studies conducted thus far, more pronounced effects of these drugs on the cognitively worse off and less pronounced effects on the cognitively better off would not increase and might even reduce social inequality. There will be no discussion of mood enhancement in this chapter. There was considerable debate in the 1900s and early 2000s about how selective serotonin reuptake inhibitors (SSRIs) might improve the mood of people not diagnosed with clinical depression. Recent meta-analyses have demonstrated that SSRIs may be no more effective than placebos in mild to moderate depression (Kirsch et al 2008; Fournier et al 2010). This suggests that anecdotal claims of enhanced mood by people who are not clinically depressed may reflect nothing more than a placebo response and not the result of the drugs effect on the brain. Much of the recent debate on enhancement has focused on moral enhancement and how psychopharmacological interventions might increase our capacity for empathy, trust, and cooperation by strengthening our capacity to respond to moral reasons for and against certain actions. The empirical question of whether and to what extent the relevant drugs could have these effects will be addressed, as well as the normative question of whether individuals would be obligated to enhance their moral sensitivity or would retain their right to refuse it.

Altering Human Nature

Opponents of neuroenhancement generally object to it for two reasons: (1) that it will fundamentally change our human nature and undermine its intrinsic value and (2) that it is symptomatic of the hubristic quest for perfection and the failure to accept the fact that much of what we do and achieve is beyond our control. In both respects, presumably neuroenhancement would have only a detrimental effect on our character and make all of us worse off than we would be without it.

The argument from nature assumes that the biological and psychological characteristics that define human nature are essentially good and accordingly should not be tinkered with. Yet the fact that the natural design of our bodies makes us susceptible to a range of physical and mental diseases clearly shows that nature is not always good. Enhancing the regenerative potential of somatic cells and tissues using induced pluripotent stem cells, for example, could benefit us by preventing or delaying the onset or progression of many diseases. In addition, enhancing our cognitive capacity to process large amounts of information and anticipate the future could improve our ability to predict pandemics and develop vaccines that could

prevent them from disabling or killing us. There may be an evolutionary advantage to enhancement. It may enable us to adapt faster to environmental changes that could threaten our survival. If we do not take any risks in trying to improve our physical and mental traits, then we may be more vulnerable to natural forces beyond our control. Altering our given biological nature can make us better off by improving our adaptability; not altering it can make us worse off in this regard. Neurocognitive enhancement would not undermine our capacity to make normative judgments about the good and bad. This capacity is not an intrinsic property of human nature as such but of an evolved cognitive and affective capacity to recognize and respond to reasons for or against actions that affect people in positive and negative ways. The fact that we can make judgments about the presumed goodness of our nature suggests that we have a conception of goodness that is independent of our nature, or at least that it is not entirely a function of it (Buchanan 2009, 2011a, b, p. 73). Insofar as enhancing our cognitive capacities made us more rational and less biased in our value judgments, it would promote impartiality and fairness in our actions and assessment of human behavior.

Claims by Leon Kass and others that human nature is good and that altering it would be bad begs the question by assuming what needs to be proven (Kass 2003). Allen Buchanan articulates the main problem with the naturalist position: “If a biomedical intervention had the unwanted consequence of destroying the capacity for judging goodness, then it would follow trivially that *this* alteration of human nature undercut our capacity for judging goodness. But it would not follow that *any* alteration of our nature would undercut that capacity” (2009, p. 150). Indeed, as noted, altering our nature in the respects that have been described could improve it and thereby benefit us. Those who appeal to human nature to criticize enhancement ignore the fact that there are both salutary and deleterious aspects to our biological and psychological design.

Michael Sandel claims that the desire to enhance our cognitive and physical capacities is driven by the desire for perfection and absolute control of our lives (Sandel 2007). We should welcome rather than try to alter our natural cognitive and physical traits, imperfect as they are. It is with reference to this that Sandel says that we should appreciate the “giftedness” of life and cultivate an attitude of openness to the “unbidden.” While it is important to distinguish between the gifted and the merely given aspects of human nature (Hauskeller 2011), Sandel is particularly concerned about the harmful effects that enhancement would have on our character.

But the desire to *improve* our capacities and character does not imply a desire to *perfect* them. Nor does it reflect a hubristic desire to completely control our lives. To cite Buchanan again: “Even in a world of pervasive and powerful biomedical enhancements, we’d still have plenty of opportunities for appreciating that many of the good things in our lives are not our accomplishments, not subject to our wills” (2011b, p. 134). Enhancement could have unintended bad effects on character. Yet it is not enhancement as such but its effects on our attitudes that would determine its value or disvalue. One cannot assume without evidence or argument that enhancement would have only adverse effects on us. It would be difficult to find anything morally objectionable about improving our character, especially if it is constituted

primarily by self-interest that neglects the needs, interests, and rights of others. Also, Sandel fails to adequately appreciate inequalities in people's natural cognitive abilities. Improving these abilities among those who are cognitively worse off could make for a more egalitarian and just society. Claims that enhancement would undermine human nature are vague and unsupported. Buchanan rightly claims that "normative essentialist appeals to human nature ought to be rejected" and that "the enhancement debate is more fruitfully pursued in other terms" (2009, p. 150). Let us now consider some of these other terms.

Cognitive Neuroenhancement

For those with normal cognitive functions, drugs such as methylphenidate, dextroamphetamine, and modafinil purportedly improve attention, concentration, and other cognitive functions associated with working memory. Yet short-term studies have shown that people with a higher cognitive baseline on an absolute scale tend to benefit less from these drugs, while those with a lower baseline tend to benefit more (Farah et al. 2004; de Jongh et al. 2008; Repantis et al. 2010). The drugs appear to display an inverted dose–response curve, with lower concentrations improving functions and higher concentrations not affecting or impairing functions. Dopamine is the main neurotransmitter targeted by these drugs. Children with attention-deficit/hyperactivity disorder (ADHD) tend to do better academically when taking methylphenidate and other stimulant medications than children with the same disorder who do not take them (Scheffler et al. 2009). These medications can improve cognitive control over their thought and behavior (Hyman 2012). But higher-than-normal concentrations of dopamine do not always improve and may interfere with some cognitive functions. Some studies have shown that methylphenidate improves cognitive functions on novel tasks but impairs functions on learned tasks (Elliott et al. 1997; de Jongh et al. 2008). So there may be cognitive trade-offs in using these drugs. Provided that the doses are low to moderate, however, there is no evidence to suggest that occasional use of these drugs in preparing for or taking an exam or writing a grant application would have any untoward effects on those who use them.

But chronic use has the potential to cause addiction and other forms of maladaptive and pathological behavior. The dopaminergic pathways targeted by these drugs play a key role in the brain's reward system. Hyperactivation of this system by consistently high concentrations of dopamine may impair inhibitory mechanisms on impulsive behavior in the prefrontal cortex and impair behavioral flexibility and voluntary control of one's actions (Volkow et al. 2009). Because some cognitive functions may be improved at the cost of others being impaired, we might have to qualify the use of "psychopharmacological enhancement." Together with the risk of addiction, chronic use of drugs like methylphenidate and dextroamphetamine would be expected to have the side effects associated with the general class of amphetamines. These would include, but not be limited to, hypertension, increased risk of stroke and myocardial infarction, insomnia, and, in some cases,

psychosis. Some people may use the beta-adrenergic receptor antagonist propranolol for cognitive enhancement. Unlike methylphenidate, propranolol does not directly affect brain mechanisms in the prefrontal cortex regulating executive functions and the capacity for attention and focus. Instead, it attenuates the autonomic response to stress by preventing or reducing a rapid heartbeat, sweating, and other bodily manifestations of performing under pressure as a concert musician or public speaker. The effects of propranolol would prevent these symptoms from interfering with the individual's focus on the cognitive tasks at hand and thereby enhance the person's capacity to execute these tasks. Yet this drug can dampen noradrenergic mechanisms in the amygdala regulating the capacity to experience fear (LeDoux 1996; Stahl 2006). This could interfere with a natural neural and psychological response to fear-inducing stimuli and put an individual at risk of harm. Specifically, by diminishing this response, the drug could cause a pedestrian to be less cautious while navigating streets in urban settings with heavy traffic volumes. Also, by taking some of the edge off of the anxiety experienced by a musician or public speaker when performing in a concert or giving a speech, the drug could attenuate the emotional valence associated with these social interactions and detract from the meaning and positive feeling they ordinarily entail.

Again, large-scale, long-term prospective studies need to be conducted to accurately assess the benefits and risks of cognition-enhancing drugs. Until this occurs, as a matter of autonomy, individuals should have the right to use these drugs if they so choose. To be sure, marketing strategies by the pharmaceutical industry touting the "benefits" of the drugs could distort the information available to those considering using them. But it would be paternalistic to suggest that these strategies would prevent most people from being suitably informed of the potential benefits and risks of enhancement. They could still freely choose to enhance or abstain from enhancing their cognitive capacities. The influence of the industry would not be sufficient grounds for prohibiting people from using the drugs. At the same time, though, those who used the drugs should take responsibility for any untoward consequences and be accountable for any social costs associated with them. Specifically, in principle they should pay for any medical care necessary to treat conditions resulting from using the drugs.

The risk of these drugs should be enough to prohibit physicians from prescribing them to individuals with normal cognitive functions. Consistent with the professional obligation to benefit and not harm patients by preventing or treating disease, there would be no justification for prescribing a drug to enhance cognitive functions if there were no disease to prevent or treat and there were any risk involved in taking it (Beauchamp and Childress 2008, Chaps. 5 and 6). Prohibiting this practice could also be justified on the grounds that prescribing cognition-enhancing drugs to healthy people with normal cognitive functions would not be an efficient use of limited resources in a publicly funded health care system (Merkel et al 2007, p. 37; Forlini et al. 2012; cf. Synofzik 2009). Of course, individuals may and indeed do often acquire cognition-enhancing drugs from acquaintances or the Internet. But professional medical ethics should prevent physicians from being an additional source of the drugs.

Some might claim that there are no substantial differences between the cognition-enhancing effects of psychostimulants and those of substances in certain foods and drinks, such as caffeine. Yet Andreas Heinz and coauthors point out that "there is a substantial difference between dopamine release caused by a particular experience of food without addiction potential and one resulting from psychotropic substances used for the purpose of neuroenhancement with respect to the extent and the habituation of dopamine release" (Heinz et al. 2012, p. 373). They add: "Dopamine concentrations, which are triggered by food, sex, and human communication, increase by approximately 50% to 100%, while drugs that directly affect dopamine transporter function (e.g., amphetamine, cocaine, and the psychostimulants methylphenidate and modafinil) induce dopamine releases ranging from 175% to 1000%. As a result, subjects learn to crave for the 'more effective' drugs of misuse and lose interest in nondrug-associated stimuli." (p. 373). Repeated use of these drugs can cause dysregulation of dopaminergic mechanisms in the brain. In addition, caffeine appears to stimulate dopamine release in the prefrontal cortex but not also in the ventral striatum, which is a component of the reward system. The effects of psychotropic drugs in the brain are more direct and pronounced than those of substances in our daily food and drink. If chronic use of these drugs inclined some people to addictive behavior, then we could question whether cognitive enhancement had a favorable benefit-risk ratio.

Research into the addictive potential of cognitive enhancement may pose an ethical problem regarding the determination of acceptable risk and the safety of the drugs. Participants in long-term studies of the drugs would be healthy subjects with no history of addiction. Those in the experimental arm of a clinical trial receiving regular doses of a psychostimulant and experiencing heightened dopaminergic effects in their brains' reward system would be exposed to a potentially addictive drug. Proving that chronic use of a drug was in fact addictive could mean causing previously healthy individuals to become addicted! Heinz et al. say that "to date no single variable has been identified that reliably predicts addiction to neuroenhancers. To identify such predictive factors, a substantial number of subjects would have to be exposed to potentially addictive drugs in prospective studies. Since these healthy volunteers do not have a disease, the risk-benefit ratio for such exposures remains rather unfavorable." (p. 374). Subjects should retain the right to participate in these studies if they are capable of giving informed consent to participate in them, and this would include being informed of any risks. But some may cite researchers' duty of nonmaleficence and question whether exposing healthy subjects to potentially addictive behavior would be consistent with this duty. With careful design and monitoring of effects in subjects, studies that quantified the risks associated with chronic use of cognition-enhancing drugs would be both empirically and ethically justified. Still, this research would require resources from public health systems. Because health resources are scarce, many would argue that research into the effects of cognitive enhancement should receive lower funding priority than research into developing preventive and therapeutic treatments for neuropsychiatric and other diseases. There is a more urgent need to generate scientific knowledge of the causes and possible treatments for these diseases than to generate knowledge about the effects of trying to improve normal brain function. Indeed, because it does not involve disease, some might argue

that research into the long-term effects of cognitive enhancement should not be funded at all.

Some opponents of cognitive neuroenhancement claim that it would exacerbate unjust social inequalities if it were practiced on a broad scale. Although people decide to take cognition-enhancing drugs for many reasons, one reason is to give them a competitive edge over others in obtaining such positional goods as an elite education or lucrative jobs. It may seem unfair that some who are already cognitively better off than others could improve their cognitive capacities. Enhancement already occurs when parents arrange for private tutors for their children or send them to private schools. It also occurs when athletes employ private trainers. So we should not focus entirely on drug-induced cognitive enhancement. But these examples of enhancement illustrate income inequalities between the better off and worse off, which suggests that it is unfair to those who lack the financial means to have these same opportunities. Nevertheless, if the positive effects of cognition-enhancing drugs are more pronounced among the cognitively worse off and less pronounced among the cognitively better off, and if the drugs were accessible to all, then wider use of the drugs by more people would not likely increase inequality and might do more to approximate a level social playing field.

If scientific studies and not just anecdotal evidence demonstrated that the drugs had positive effects on executive functions, then some students, university teachers, and other workers might feel coerced into taking the drugs just to keep up with their cognitively enhanced peers. Employers might pressure employees to take the drugs in order to work more efficiently and productively. This already occurs to some extent in the military. Some personnel are encouraged or required by their superiors to take modafinil or other stimulants in order to perform certain tasks over long periods without the need for sleep. Some workers might decline to take the drugs out of concern about potential deleterious effects on their bodies and brains. This could put them at a competitive disadvantage compared with those who took the drugs. Whether these concerns were warranted would depend on the actual effects on neural and cognitive functions. On the basis of meta-analyses of the effects of methylphenidate and modafinil in healthy individuals, psychopharmacologist Reinoud de Jongh and coauthors state: “High expectations regarding the effects of enhancement drugs are not warranted. However, societal pressure may occur with respect to drugs that are ineffective or only slightly effective simply because people believe these drugs improve performance, as the illicit use of methylphenidate and modafinil shows. Creating realistic expectations appears to be very hard to accomplish” (de Jongh et al 2008, pp. 771–772; see also Repantis et al. 2010; and Lucke et al. 2011).

Coercion can result from unreasonable expectations impose by some on others, forcing them to accept situations that are worse for them than any alternatives. But if everyone were suitably informed of the generally modest effects of psychostimulants on cognition, then expectations about these effects would adjust accordingly. Consequently, the incidence of real or perceived coercion or unfairness regarding the use of these drugs would diminish. Moreover, drugs that enhanced the relevant cognitive capacities would not alone determine a better or

worse outcome. Individual effort in exercising these capacities and time management would also be necessary. The student would still have to write and submit the term paper on time, and the researcher would still have to write and submit the grant application by the deadline. Another factor to consider is that enhancing cognitive capacities by itself would not necessarily make our lives better on the whole, since well-being is more than a function of these capacities (Tannsjo 2009).

In 2008, a group of neuroscientists and ethicists formulated a set of recommendations based on the presumption that mentally competent adults should be able to engage in cognitive enhancement (Greely et al 2008). These recommendations included an evidence-based approach to the evaluation of risks and benefits and enforceable policies regarding the use of cognition-enhancing drugs to support fairness, protect individuals from coercion, and minimize enhancement-related socioeconomic disparities. Even if the risks were proven to be significant, it would not be clear whether this would warrant a limitation or prohibition on enhancement and whether competent, autonomous individuals could lose their right to enhance. This would come with the proviso that they would be responsible for any social costs resulting from enhancement.

Moral Enhancement

A potentially more beneficial intervention in the brain and mind would be psychopharmacological enhancement of our moral disposition and sensitivity in recognizing and responding to the rights, needs, and interests of others. This would involve not only improving the cognitive capacity to respond to reasons but also the affective capacity for social emotions such as shame, regret, and remorse. It could improve the cognitive capacity to imagine counterfactual situations, making us more cautious in deliberating about which actions to perform. It could also improve the ability to foresee the probable consequences of our actions. Increasing our capacity for extended empathy, trust, and cooperation could result in moral progress by promoting behavior that would reduce the incidence of humans harming other humans and result in greater well-being for all (Douglas 2008; Spence 2008; Persson and Savulescu 2011, 2012; Harris 2012). Among other things, enhancing our moral capacity could be an antidote to the excessive competition and pervasive cheating in academia and sport that have been associated with enhancing cognitive functions.

As with cognitive neuroenhancement, genetic and pharmacological modification of our moral thought and behavior have been suggested as different possible ways of producing the desired effects. Genetic modification of the neural processes mediating our moral sensitivity would not likely be feasible. Our neural and mental characteristics are not just a function of our genes but also of epigenetic factors associated with our bodies and the environment. Genotype does not determine phenotype. So even if genes or gene products associated with behavior could be delivered safely into the relevant regions of the brain, this would not ensure that the individual would display enhanced moral behavior. In light of these and other

considerations, Buchanan says: “My hunch is that widespread genetic enhancements of humans will not occur for a long time, if ever” (2011b, p. 100). Psychotropic drugs targeting particular neurotransmitters would have more direct effects in the neural networks mediating moral capacity, and these effects could be monitored in real time with functional neuroimaging.

Good bioethics relies on some degree of speculation in anticipating ethical issues arising from biotechnology. On the issue of moral enhancement, however, we need to be careful not to put the conceivability-driven ethical cart before the empirical horse. In their recent book, *Unfit for the Future*, Ingmar Persson and Julian Savulescu claim that it is possible to change our moral attitudes to avert threats from weapons of mass destruction and environmental degradation to our well-being and survival (Persson and Savulescu 2012). They also claim that it is conceivable that a pharmaceutical could cause the chemical changes in our brains underlying these attitude changes. Given the urgency of the threats they describe, they say that if it were feasible, effective moral bio-enhancement would be the most important kind of biomedical enhancement. Few would disagree in principle with the idea that we should enhance our capacity for moral reasoning and behavior to reduce or prevent the harm that we cause to present and future generations. But one crucial question is this: How would psychopharmacology induce the necessary neural and attitudinal changes to meet these challenges? Conceivability alone does not provide an adequate framework within which to discuss the ethical issues. Empirical data on the neural targets and psychological effects of selected drugs is needed.

Some studies suggest that increasing concentrations of serotonin in the prefrontal cortex could induce or increase harm aversion and make us more likely to respond to moral reasons against actions that adversely affect others. The SSRI citalopram (Celexa) has been shown to enhance social cognition and promote pro-social behavior by increasing the capacity for harm aversion in healthy subjects (Crockett et al 2010; but see also Chan and Harris 2011). Yet the fear and impaired empathy associated with harmful behavior are mediated by subcortical more so than by cortical brain regions, where serotonin is particularly abundant. The cognitive and affective capacities necessary for moral reasoning are mediated by distributed neural networks in interacting cortical and subcortical regions. The amygdala and anterior cingulate cortex are particularly relevant to fear and empathy. It is doubtful that the effects of a drug targeting serotonin concentrations in the prefrontal cortex would project to these other regions and influence other neurotransmitters modulating fearful and empathic responses.

A drug might produce these modulating effects by increasing concentrations of oxytocin in the brain. There is emerging evidence that this neuropeptide plays a critical role in social cognition (Ross and Young 2009). A drug administered intranasally that increased oxytocin in the brain could promote pro-social behavior and enable us to move beyond self-interest and group bias. Oxytocin interacts with the hypothalamic-pituitary-adrenal axis to inhibit activity in the amygdala mediating the fear response. By diminishing this response, it is possible that such a drug would increase the cognitive-affective capacity for concern, trust, and cooperation. Another neuropeptide, vasopressin, appears to function in the same way. Yet the salutary

effects of drugs aimed at increasing levels of these neuropeptides cannot be assumed. For example, some studies suggest that social context can influence the effects of oxytocin on people's behavior. This may involve how one perceives others, which can be a function of the social group to which they belong. The drug may strengthen the experience of bonding with others in groups with which one identifies and contribute to the perception of those outside these groups as competitors or threats. In some cases, social factors may cause oxytocin to promote mistrust and antisocial rather than pro-social behavior (Bartz et al. 2011). There are questions about the safety and efficacy of chronic administration of oxytocin and vasopressin, which can only be answered after more long-term controlled clinical trials have been conducted.

Given the extent of actual and potential harm resulting from the failure to recognize and respond appropriately to the rights, needs, and interests of others, there are compelling reasons for developing and implementing safe and effective moral enhancement. But at least four issues would have to be addressed and resolved before doing this.

First, extensive research would have to be conducted to identify a drug or drugs that would safely and effectively enhance our moral sensitivity. This would be costly, and it raises the same question as the earlier question regarding research on cognition-enhancing drugs: Should research into psychopharmacological agents designed to enhance our moral behavior be treated on a par with research designed to prevent or find treatments for neuropsychiatric and other diseases? Some would argue that the harm resulting from actions symptomatic of our limited moral compass is as significant as, if not more so than, the harm from disease. But the immediacy and salience of the latter appear to give it more medical and moral weight. What complicates drawing accurate and fair comparisons between them is that these are distinct types of research with distinct aims. Professional and public debate will be necessary to decide whether priority in resource allocation should go to research aimed at ameliorating flaws in our bodies and brains or to research aimed at ameliorating flaws in our character.

Second, it is doubtful that pharmacological modification of our cognitive and affective capacities alone would make us more responsive to moral reasons when acting. Education thus far has failed to do this, as Persson and Savulescu point out. Yet the right type of education could complement psychopharmacology in making us more responsive to the interests of those who exist now and those who will exist in the future. The social environment also influences brain function and provides cues that prompt us to act in different ways. Moral enhancement would thus require a full complement of education, environmental modification, and psychopharmacological intervention.

Third, just because a drug might enhance our capacity for empathy, trust, care, and concern for others does not mean that we would exercise this capacity. We may fail to put the necessary effort into translating receptivity to moral reasons into morally defensible actions. Factors in the social or cultural environment often motivate us to act. Yet all too often these factors incline us to self-interest and group bias. It is unclear whether or to what extent the appropriate drugs could weaken the influence of these factors on our behavior. Indeed, as I have noted, drugs such as oxytocin may

exacerbate this bias. These considerations reinforce the earlier point that enhancement of our moral attitudes would depend on a tripartite model of education combined with modification of the social environment and our cognitive and affective capacities. Alluding to this idea, Buchanan says that “a biomedical intervention might be one aspect of a multifaceted effort to extend concern and respect for all human beings, not just those who are like us” (2011b, p. 170).

Fourth, some proponents of moral enhancement insist that it must be a collective enterprise in which people are not merely permitted but obligated to enhance their cognitive and affective capacities (Harris 2007, 2011, 2012; Persson and Savulescu 2012). Reducing or averting harm from the most serious threats to our well-being and survival is a collective action problem. As such, this and related goals can only be achieved if a sufficient number of people engage in moral enhancement. Given the choice, though, many people would decide not to enhance because they lacked the motivation to strengthen their moral disposition. If a significant number of people opted out of enhancement, then it could preclude the collective effect from being achieved. There would also have to be agreement on which attitudes or virtues should be enhanced and which vices should be diminished. This would presuppose a common understanding of the concept and goals of moral enhancement by the general public. It cannot be predicted or assumed that this critical agreement could be achieved. In addition, there would have to be agreement on which drugs would be most likely to safely and effectively enhance the disposition to be moral. Among other factors, this would assume that pharmaceutical companies producing the drugs would be acting in good faith.

Assuming that there could be public consensus on these issues, making moral enhancement mandatory rather than voluntary would involve a different and more controversial set of problems. It could mean that individual liberty in choosing whether or not to enhance could be overridden by collective interest. This would be a violation of the presumptive right to noninterference in one’s body, including the brain and mind. Given the magnitude of the actual harm from people failing to respect the rights and interests of others, the potential harm from the use of weapons of mass destruction and environmental degradation, and assuming that psychopharmacology could improve our moral behavior, some restrictions on individual liberty in choosing not to enhance might be justified. The core concern is not the benefit-risk ratio in using psychoactive drugs but more fundamentally the right to refuse what may be a beneficial intervention for individuals and society. Even if some restrictions on individual liberty for collective benefit were intuitively acceptable, we would still have to identify, collectively agree on, and morally and legally justify what these restrictions would be.

Conclusion

I have considered the respects in which our cognitive and moral capacities can be enhanced through psychopharmacology. After examining the empirical issue of how drugs might enhance these capacities, I considered some of the ethical reasons

for and against enhancement. Claims that enhancement would result in a deleterious alteration of human nature, and that it would involve a hubristic pursuit of perfection, are unfounded. Instead, what matters morally is whether drugs altering our neural and mental functions would have unintended bad consequences on these functions. I noted evidence pointing to the potential of cognition-enhancing drugs to cause addiction. Citing the recommendations of an eminent group of neuroscientists and ethicists, I also noted that questions about the safety and efficacy of these drugs could only be answered after a significant number of long-term studies had been conducted. There are ethical questions about the research itself, since it would involve healthy subjects who might be exposed to a risk of addictive behavior by participating in these studies. Given limited health resources, there is the additional question of whether funding research into improving normal neural and mental capacities could be justified.

Moral enhancement has the potential to be significantly more beneficial than cognitive enhancement because it could have positive effects on large numbers of people in reducing harm, increasing well-being, and averting threats to the survival of human and nonhuman species. By improving our moral sensitivity, it could promote moral progress. Normative questions about whether we should enhance our capacity for empathy, care, and trust would depend on empirical evidence showing that certain drugs could produce these changes in our attitudes toward others. Some have argued that the collective effects of moral enhancement that are necessary to avert the gravest threats to our survival can only be achieved by requiring individuals to engage in it as part of a collective enterprise. This may involve some restrictions on individual liberty and the presumptive right to refuse an intervention in one's brain and mind. Not everyone would agree that the interests of the collective could justify limiting the rights of individuals to refuse enhancement, even if it had great promise in making all of us better off. Given the prospect of moral enhancement, the ethical challenge would be to strike the right balance between respecting the rights and interests of individuals and those of the human community. Only by striking this balance can moral progress be made.

Neurolaw

Neurolaw: Introduction

81

Reinhard Merkel

Contents

Abstract

In recent years, a host of normative questions have surfaced in the wake of rapid progress in the neurosciences and have entered the sphere of legal discourse. They continue to confront legal scholars and increasingly also courts with problems that strike many lawyers as rather unfamiliar within their accustomed domain. Some of these problems seem to be entirely new, others appear to shed new light on venerable and unresolved matters of the law and its philosophical foundations. In a rough and ready differentiation, one can distinguish three perspectives from which to assess these developments. Neuroscience provides (1) new insights (into old metaphysical problems of mind and brain), (2) new ways to peer into, and (3) new ways to intervene in the brain (and hence, perhaps, the mind). The realm of (1) may be fittingly exemplified by the recent outpouring of neuroscientific contributions to the age-old philosophical question of freedom of the will and the attached problem of legal responsibility; (2) refers to new methods of neuroimaging, visualising structural as well as functional features of the living (and working) brain; and (3) points, most notably, to new ways of enhancing mental capacities of healthy people by altering neural circuits in their brains. – Each of the entries in the present section contributes to (at least) one of these spheres of new questions.

Christoph Bublitz and Martin Dresler deal with legal problems posed by possible manipulations of memory. Memory is not a single entity but a complex phenomenon encompassing several mental capacities and various subjective states of

mind. Many of its puzzling features, therefore, belong to the perennial problem of the relation of mind and brain, though up to now it has been treated rather stepmotherly by professional philosophers of mind. By contrast, empirical, particularly neuroscientific research on memory has remarkably blossomed within the last decades. It has produced a host of results that more or less directly affect concerns of the law.

Legal systems, especially in their procedural parts, rely on accurate memory functions in a number of ways, e.g., on memories of witnesses or of victims of crimes. Over and above this concern for its own functioning, however, the law may also have to engage with memory as a constitutive feature of personhood, indispensable, e.g., for the autobiographical "self" of persons. For this part of memory has become vulnerable in recent years, and hence a legitimate objective for an individual claim to legal protection. As Bublitz/Dresler point out, neuroscience might be on the brink of the capability of modulating memories in various ways, most notably by erasing them, altering or editing their content, or attenuating their vividness.

The authors start with elucidating the phenomenon of memory as well as the corresponding concept by a set of empirical and conceptual distinctions. "Memory" comprises a bundle of functionally different (though related) capacities and, accordingly, of referring concepts – e.g., "declarative" (semantic, episodic, autobiographic) as opposed to "non-declarative" memory (internalized in certain physical skills acquired over one's life course). Phases of acquiring, storing and recalling memory are distinguished. The underlying neural processes do not take place in neatly separable areas of the brain but rely on complex neural networks and their multifarious interactions. "Forgetting" as the factual and conceptual counterpart of memory is also analysed in its accordant manifoldness. It ought not to be conceived of simply as a mental deficit. On the contrary, to some extent and within normal limits it fulfills important purposes indispensable for our psychic well-being. The authors demonstrate that, rather than being opposites, remembering and forgetting are complementary processes which should both be valued in their own right.

Neuroscientific memory research is still in its infancy; many empirical questions are not well understood yet. However, certain forms of memory have already become accessible to altering interventions from outside, in certain contexts even without the affected person's awareness. Memory alterations might occur in the form of enhancing, diminishing (even erasing) or changing the content of memory. All of them obviously raise challenges for ethics and law.

Bublitz/Dresler begin with an ethical analysis. Part of it gains acuteness by being contrasted with the report "Beyond Therapy," published in 2003 by the U.S. "President's Council on Bioethics." This report postulates an almost sacrosanct duty of individuals as well as societies to "remember fitly and truly" their own past and to not employ neurotechnical means to tinker with memories. Of course, interests of individuals in developing and maintaining a coherent self *prima facie* also speak in favour of preserving accurate reminiscences of one's own past. On the other hand, persons may have experienced severely traumatic events that threaten

their present and future well-being, and hence have legitimate interests in numbing or erasing the corresponding stressful memories.

Bublitz/Dresler reject the President's Council's strong demand and make normative room, as it were, for a moral right to intentionally amend one's autobiographical memory in order to overcome traumatic experiences casting shadows on one's future flourishing. They defend their position in light of moral demands concerning identity, personality and *prima-facie* obligations of persons to promote their mental development. They do, however, concede various dangers associated with unwise memory alterations, but deny a thoroughgoing moral obligation to leave the natural interplay between one's autobiographical remembering and forgetting untouched. There can be good moral reasons to artificially alter one's memory.

An analysis of questions of law follows. The authors underscore the law's primary task, which is not to warrant "good acting" of its subordinates but rather to maximize reciprocal individual liberty in a peaceful society. Hence, the realm of legal freedom is not coextensive with that of morally approved actions. The advent of methods of intervening in the brain and thus the mind gave rise to heretofore unknown problems of safeguarding the mental sphere. Some mental liberties, such as freedom of conscience and thought, have long been placed beyond governmental control by international covenants or national constitutions. Memory, however, is not among them. States have always taken an interest in acquiring knowledge of certain past events by interrogating witnesses. This evinces a public interest in having memories of people preserved within their natural limits. Individuals, of course, also have strong interests in not becoming targets of external memory interferences that they did not consent to. On the other hand, they might also wish to not be legally deprived of their liberty to give such consent when they want to alter their own memories.

This gives rise to a host of questions of legal theory concerning rights and duties (and their respective limits) of states and of individuals. Bublitz/Dresler analyse such questions with regard to interventions in personal (and, in part, collective) memories. Their starting point is Adam Kolber's proposal of a novel right to "freedom of memory." Decidedly sympathizing with such a right, the authors survey its potential scope which would presumably encompass a right to remember, an accompanying legal protection against memory erasure and (arguably) also a right to enhance one's memorizing capacities. But it might well extend beyond that and also protect a right to forget which deserves legal protection as well. Besides a right to have one's own memories erased at will, it presumably covers a right to not being reminded of something one wishes to forget or has, albeit artificially, already forgotten. This latter right, however, must be balanced against various liberties of others, such as the right of free speech, even if making use of such liberties reminds others of things they want to (and have a right to) forget.

The authors discuss a few more possible limits to that right, some of them originating from public interests which in certain contexts do prevail over individual liberty rights whereas in others they do not. Finally, Bublitz/Dresler turn to the question whether legal responsibility might potentially be affected by memory

modulations. A legal duty of wrongdoers to memorise their deeds in order to preserve their bad conscience is rejected (though an analogous moral duty may exist). Hence, a corresponding right of the state to interfere with a perpetrator's attempt to artificially rid themselves of their guilty memories is denied. In their concluding remarks, the authors underscore the future task of legislators, courts and legal scholars to address problems of memory manipulations much more thoroughly than has been done so far.

In his second contribution, which he authors alone, Christoph Bublitz approaches the fundamental question of cognitive liberty. His considerations are premised on the conviction that legislators around the globe face the inevitable challenge of regulating novel neurotechnologies. This holds, on the one hand, for private use of such technologies, but also for various purposes of the state that may touch upon much more sensitive issues, such as coercive mind-interventions supposedly in the public interest. On that occasion, existing legislation may come under critical review.

The author begins his exploration by pointing out some basic legal principles that pertain to a possible right to cognitive liberty. In liberal democracies, the powers of governments are limited, most importantly by constitutional and human rights law. Interferences with rights guaranteed by constitutional and human rights law have to be justified by prevailing interests. Some constitutional guarantees cannot be interfered with at all. Neuroethical proposals of whatever kind and associated policy recommendations cannot be transformed into law unless they conform to these legal boundaries.

Thus the law must identify and define the fundamental rights possibly affected by state actions more precisely. In the present context, this holds with respect to cognitive liberty on the one hand and to forms of interferences with other people's minds on the other. Currently, the legal situation is unclear in some important aspects – not only for the trivial reason that national legal systems vary, but also because the legal parameters of conduct affecting one's own or other's minds are not sufficiently explored. Cognitive liberty is one of the rights that (actual or potential) regulations of neurotechnologies or governmental powers to intervene into citizen's minds might interfere with. As Bublitz points out, while references to cognitive liberty are rather common in neuroethics, its legal meaning, scope and limits are only poorly defined. Many national legal systems do not recognize such a right. However, in the major human rights treaties cognitive liberty is firmly entrenched under the name of freedom of thought.

The author explores some of the important normative aspects of the right. In theory, it provides far-ranging protection against many types of unwanted mind-interventions. In practice, however, the right does not play an important, not even a respectable role. As Bublitz makes clear, it is a neglected, perhaps an even largely forgotten human right, more of a vague principle rather than an enforceable legal claim. It has thoroughly failed to be effective in many contexts that would seemingly provide genuine fields of its application, such as coerced psychiatric treatment or national drug policies. Many lawyers or policy makers may not even have heard of it. The task for legal theory is therefore to provide an interpretation of the right

that lives up to its importance, and, more generally, to argue for its recognition in national legal systems.

The author shows that the right has various roots in pre-constitutional days. He explores some of its ancestry and outlines various classic arguments, for instance of Kant and Mill, for its recognition. He argues that its acknowledgment is not merely a contingent political matter, a claim one may favour or reject depending on one's political taste, but rather that it is an inevitable presupposition of any liberal legal system deserving this label. Bublitz forwards some suggestions pertaining to a solid construal of the right and identifies open questions in this context. Furthermore, he develops a specifically legal (as opposed to ethical) view on a contentious neuroethical issue: whether old (traditional) and new (high-tech) means of intervening into other people's minds are intrinsically different or should be judged and treated on par. He shows that there are indeed significant differences from a legal perspective, having to do not so much with the (possibly equal) effects of intervening actions on other's minds, but rather with fundamental liberties of the intervener in making use of the common public space. It is one thing, the author contends, to use one's freedom of speech and provide convincing arguments in order to change other people's opinions even against their previous will, but quite another to bypass their sensory control and implant a new opinion directly in their minds by altering their brains without their prior consent.

Bublitz recurrently tackles one of the salient features of freedom of thought in human rights law, namely that it is protected unconditionally. That is to say that in theory interferences cannot be justified for any reason whatsoever. As a consequence, the law primarily regulates external behavior of citizens, but abstains from ruling their minds. However, this raises an important question: whether such a strict protection of the mind should be maintained. Current legislation demonstrates that many concerns may not be adequately addressed if states do not have any competency at all to restrict the mental freedom of the individual in at least some respects and with regard to at least some pressing issues, such as paternalistic interventions to safe a person from the self-infliction of grave harms.

However, as Bublitz insists, consigning governments the power to alter the minds of their citizens constitutes "a paradigmatic shift from governing conduct to governing minds with far-ranging implications" in various fields of the law and of civil society. It should and hopefully will prompt controversial discussions between ethicists, legal scholars, courts and, last not least, the public.

Reinhard Merkel investigates problems that in all likelihood will be posed to the law by the rapidly developing methods of neuroimaging. This topic belongs to the second sphere of our tripartite scheme of neuroscientific challenges to the law delineated above: that of new ways to peer into the brain and hence arguably the mind. The author confines his analysis to criminal law as his normative, and to functional (as opposed to structural) magnetic resonance imaging (fMRI) as his neuro-technical subject. Though public and civil law will also be affected by developments in neuroimaging, this impact, the author contends, will not be as profound and puzzling as in criminal law. Within the sphere of the criminal law, he focuses on two topics of particularly crucial importance: (1) brain-based lie

detection in criminal proceedings, and (2) "neuroprediction" of future dangerousness of perpetrators, a problem that may become relevant either in the sentencing phase of criminal trials (as in common law jurisdictions) or in special proceedings of preventive detention after a prison term has been served (as in many continental legal systems).

The author begins with a sketch of the intricate basic science involved in fMRI and points out the particular strengths and limits of the method. Then turning to the problem of neuroimaging of deception in court, he analyses problems of validity and reliability of fMRI. The widespread claim that the scientific suitability of the method for any evidentiary purpose in criminal trials is to be denied in toto, is criticised as overreaching. There is, the author holds, no such thing as a uniform standard of validity applying to all probative aims pursued by the parties to the various phases of criminal proceedings. The defendant or his counsel does not have to prove his innocence, whereas proof of the opposite, his guilt, "beyond reasonable doubt" is what falls on the part of the prosecution and finally of jurors and judges. This asymmetry in evidentiary burdens between the two parties has consequences for the question of what is a sufficiently valid scientific method for either of them. Since the benefit of the doubt is on the side of the defendant (but not of the prosecution) and his own aim defined by the modest need of casting only some such doubt on jurors' convictions of his guilt, fMRI might well be an entirely appropriate method for this goal, and providing even weak circumstantial evidence for his veracity of at least some avail to his end is certainly admissible. At the same time, fMRI is as yet unsuitable and hence inadmissible for prosecutorial probative aims. Or so the author contends.

He then considers the widespread skepticism concerning "seductive allures" ascribed to fMRI: its potential to mislead jurors and judges into believing that what they see are a kind of scientifically objective "snapshots" of what happens in a brain during its engagement with cognitive tasks. The author proposes to counter the risk of such crude misunderstandings not by precluding the entire option for defendants (who have a right to provide even weak evidence for their case), but rather by instructing jurors and judges adequately, explaining to them what the images of an fMRI do and what they do not show, and emphasizing that in any individual case their probative value is low. The author concludes his vote for a limited admissibility of fMRI for lie detection with a set of caveats that must be observed in order to avoid any misguided naiveté on the part of the legal personnel.

There is, however, a principled concern which Merkel addresses subsequently. Assuming that in the not too distant future fMRI will become capable of ascertaining thoughts (and lies) with a high degree of validity even from uncooperative suspects, would it then be legitimate to introduce it in criminal proceedings as a regular (if needed, coercive) means of evidence for prosecutorial purposes, too? The author distinguishes between coercing suspects and witnesses. He denies a right of the state to force defendants to undergo fMRI for lie detection, as this would violate their basic right against compelled self-incrimination. Here the following problem arises: defendants' bodies may well be thoroughly examined for evidentiary purposes. Not so their minds, at least not as far as access to their mental

sphere can only be procured by their own compelled cooperation. In other words, testimonial information from suspects must not be obtained coercively, whereas physical information from their bodies may. Now, fMRI for lie detection seems to do both at once: procuring testimonial information (knowledge, memory etc.) by investigating only the part of one's body where such information is stored and from which it can be inferred – the brain.

The author argues that neuroimaging of deception must be classified as obtaining testimonial information. In such cases, the brain is not searched for any of its physical features, but only to gain access to the corresponding mental processes. Hence, compelled fMRI of deception would violate a defendant's fundamental privilege against self-incrimination. Witnesses, on the other hand, do not have such a privilege. They must not refuse (or give untruthful) testimony. Provided that some years from now even coerced fMRI will fulfill standards of validity, it might be argued that witnesses could become legitimate objects of compulsion to testify in a bran scanner. Merkel emphasizes, however, that liberal states should abstain from such a practice. Controlling the access to one's mind is a constitutive feature of personhood. States should not coerce anyone into a brain scanner.

The author concludes with an analysis of the problem of "neuroprediction" destined to assess the future dangerousness of individuals. In such cases, what is at stake is not punishment for a committed crime, but detention for something one has not done (and is only feared to eventually do). Since such treatment of citizens inevitably leads legal orders to the limits of their legitimacy, states are obliged to exhaust all available and suitable methods to clarify the underlying prognoses. Currently, this is regularly done by obtaining the expertise of (usually two) psychiatric expert witnesses. Since such prognoses are contentious and error-prone, Merkel argues for even a duty on the part of the state to adduce further prognostic indicia, provided they meet basic standards of validity. There is scientific evidence that fMRI may already (or in the foreseeable future) meet such standards with regard to two types of potentially dangerous dispositions: pedophilia and psychopathy. Merkel concludes that if this evidence is confirmed, fMRI will indeed be on the brink of entering legal procedures – and vis-à-vis the inevitable problem of assessing future dangerousness for preventive detention, rightly so.

Imogen Goold and Hannah Maslen tackle a question that has arisen with the advent of new ways (real or potential) of intervening in the brain in order to enhance one's mental, most notably cognitive, capacities. Would such enhanced abilities be accompanied by an enhanced legal responsibility when they are (or, at any rate, could be) deployed to fulfill demanding duties that are prone to fault and hence to legal liability? And could there be a legal obligation to take such an enhancer provided it were effective and posed no unreasonable risk? The authors analyse these questions with regard to the English law of negligence only. But since its principles, by and large, are based on fundamental principles of fairness, they can be taken as widely representative for many other legal orders as well.

Goold and Maslen open up their enquiry with a range of quotations from the medical as well as neuroethical literature in which legal requirements to take

enhancers in situations of impending fatigue are called for, most notably for medical doctors. Could there be such an obligation? And could someone be legally liable for a harm that might have been prevented had he or she taken such an enhancer? The analysis centres on three basic questions: First, “the duty question” – is there a duty to take an enhancer (accompanied by a liability for omissions)? Second, “the breach question” – does failing to take the enhancer amount to a breach of the standard of care? And third, “the causation question” – can it be proved that the omission caused the harm?

The authors explore these questions by deploying a hypothetical scenario: a fatigued surgeon after 36 h of work without rest is confronted with an emergency case requiring an immediate surgical intervention that would take about 2 h and that only she is qualified to perform. Though being badly exhausted, she does have a duty to perform the surgery and she would be legally liable for an omission were she to refuse it. She knows that she could take an enhancer. Would the failure to take it constitute a breach of her duty?

The relevant legal standard of care is not determined by the common *factual* practice in hospitals (which at present would certainly not include taking enhancers). Instead, it must be adjusted to the hypothetical measure of a *reasonable* practice, above all with regard to a fair and sensible balancing of risks and benefits. After pondering various arguments, especially that of some non-trivial risks posed by the enhancer to the surgeon’s own health, the authors conclude that currently English courts would be unlikely to hold her responsible for refusing to take it.

Even if that legal hurdle could be overcome, say, with safer enhancers of the future, the subsequent causation question is hard to answer in the affirmative. On a Humean (i.e., counterfactual) account of causality, tacitly adopted by most jurisdictions, an omission is causal for a harmful effect only if the harm would not have occurred “but for” (or without) the omission, i.e., it would have been prevented by the required action. This is problematic here in two regards: First, can it be ascertained “beyond reasonable doubt”? For obvious reasons, that seems hard to do. How does one *prove* what has not, but only could or would have, happened had the course of events been different? And secondly, since every surgical intervention bears risks that may materialize without any fault on the part of the surgeon, the harm could have occurred anyway, even if the enhancer had warranted a faultless performance of the surgery.

The authors then turn to the problems that arise when enhancers cause harm. Could taking an enhancer amount to a breach of duty? (Would it be an *enhancer* then?) Goold and Maslen give a negative answer. Even if causality could be proved “beyond reasonable doubt,” the liability of the surgeon would have to be denied. The harmful effect as a specific consequence of an enhancement (supposedly designed to prevent such effects) appears to remote to be imputed to the person who took it.

After briefly considering and denying an enhanced legal responsibility as a corollary of artificially lifting oneself above the threshold of the regular standard of care, the authors conclude their explorations with thoughts on the divergence

between ethics and law. Though there might be good ethical arguments in favour of a duty to enhance oneself in stressful, error-prone and potentially harmful situations, the law still has good reason to eschew an analogous legal duty and a corresponding liability. Legal and ethical rights and obligations pursue different goals. Whereas the former aims to guide "the good deed," the latter's task is to maximize equal individual liberty. Hence, currently the law (not only in England) is unlikely to find surgeons liable for negligence when they take, or fail to take, mental enhancers.

Elizabeth Shaw addresses the controversial topic of brain interventions in rehabilition programmes for criminal offenders. At the outset, she presents potential aims of neurointerventions: increasing empathy, decreasing violent and sexual urges and even racial sentiments, strengthening willpower as well as enhancing cognitive abilities. If safe and effective means are developed in the future, a host of ethical and legal questions arises. Shaw addresses and ultimately dismisses the most prevalent ethical criticisms of "moral enhancement." In light of the law, interventions were particularly worrisome if they affected a person's status as a moral agent by undermining their free will. However, so Shaw argues, the interventions available today or in the near future do not globally weaken capacities for autonomy.

The most controversial – and as yet not thoroughly addressed – form of changing offenders are mandatory interventions. As part of their punishment, states might sentence offenders to undergo neurointerventions. Shaw enumerates several arguments for and against compulsive treatments. For one, in some jurisdictions sexual offenders are treated against their will, sometimes with profoundly invasive methods. Furthermore, neurointerventions might be a more humane treatment than incarceration (or castration, as the case may be), given the situations of prisons in some countries and the physical and psychological effects of long-term imprisonment. In addition, by drawing on John Rawls' thought experiment of the "original position" in which future citizens of the community to be (or rather their proxy) design social rules from an impartial perspective behind a "veil of ignorance," some theorists argue that consenting to such treatments might be in the best interest of offenders and can hence be normatively presumed. Others, more harshly, suggest that offenders have simply forfeited their rights against being subjected to neurointerventions. Finally, interests of third parties might be taken into account, such as potential victims, families, or the public (as imprisonment is exceedingly expensive).

However, strong arguments speak against mandatory interventions. Shaw highlights the risks of misuse if states were to acquire the power for invasive intrusions. She presents two arguments, based on a retributivist and a non-retributivist position on punishment that both provide strong reasons against mandatory interventions. In addition, the author reminds us that state's powers to punish are limited. The 8th Amendment of the US Constitution, for instance, prohibits "cruel and unusual punishment." In other jurisdictions, the inalienable right to human dignity might be affected by sufficiently invasive interventions because they may be viewed to objectify offenders. Furthermore, Shaw is critical of the often and all too easily drawn analogy between incarceration and neurointerventions. While the former

only restricts freedom of movement, neurointerventions encroach upon essential characteristics of the person which are often conceived of as being, for principled reasons, beyond the reach of governmental control.

In the face of these objections, the best way might be to offer neurointerventions on a voluntary basis. Besides some familiar questions of informed consent, the special context of prisons might, however, cast doubts on the "real" voluntariness of offenders' consent. Shaw engages with threats and inappropriate offers and draws distinctions between different aims of the intervention. Whereas experimental interventions in exchange for early release may take unfair advantage of the offender's situation, the state is entitled to offer interventions targeting the psychological sources of the behavior for which the offender was sentenced. For if the incarceration (as the only alternative to the brain intervention) is the result of the proper application of a legitimate legal order, it should not be considered analogous to (illegitimate) pressures from other people, but rather akin a necessitating situation originating from one's natural "bad luck." After presenting further arguments of the current debate, the author concludes that under certain conditions neurointerventions can and should be offered by the state as long as they remain respectful of the offender's status as a moral agent.

Contents

Abstract

Neuroscience might develop interventions that afford editing or erasing memories, changing their content or attenuating accompanying emotions. This section provides an introduction to the intriguing ethical and legal questions raised by

such alterations, with a special focus on the report of the President's Council "Beyond Therapy" and the proposal of a right to freedom of memory advanced by Adam Kolber.

Introduction

Memory is a marvelous capacity. It allows representing the past and adapting future behavior in light of prior experiences. In a more colorful way, it is described as "mental time travel" (Tulving 1985) or "the presence of an absent thing stamped with the seal of the anterior (Ricoeur 2004, p. 17)." Memory is a multifaceted phenomenon, not a single entity but a bundle of functionally distinct yet interwoven capacities with different neurophysiologic foundations that enable the most basic forms of learning such as classic conditioning as well as reminiscing about the trajectory of one's life.

Current memory models differentiate several systems by content (LeDoux 2007): Declarative memory comprises semantic, autobiographic, and episodic contents that can easily be verbalized, whereas non-declarative memory stores motor or perceptual skills and conditioned stimulus–response patterns which can be behaviorally expressed but hardly articulated. Thus the verb "to remember" does not denote a single activity but comprises, e.g., the ability to express acquired procedural skills and factual knowledge as well as reexperiencing the past with that distinct phenomenal quality for which Elving Tulving coined the term "autonoetic consciousness" (Tulving 2002). In the following, we shall be primarily interested in the latter.

Further distinctions are drawn between temporal phases and processes. Memory content has to be acquired, stored, and recalled – accordingly, encoding, consolidation, and retrieval constitute the three main phases of memory. Directly upon encoding, memory traces are labile and prone to rapid decay. Most items in working memory (e.g., after perception) are never processed further; only some are transferred into long-term memory. During this process of consolidation, neural memory traces – also called "engrams" – are organized and stabilized. How memories are exactly stored remains a mystery and seems to differ for various types; the search for the engram is still on (Thompson 2005; Hübener and Bonhoeffer 2010). By all we know, memories are not stored in easily localizable brain structures but rely on networks of multiple brain areas and changes in the synaptic strength between neurons. The terms storage and consolidation suggest that contents of memory become permanently fixed traces in the brain, insensitive to modification, stored away until retrieval. However, such a static picture misses the dynamic and changeable nature of memories: During the retrieval process, sometimes induced through conscious effort, sometimes involuntarily, the engram seems to return into a temporarily fragile state and undergoes another process of consolidation (called reconsolidation) afterwards (Dudai 2012). Reconsolidation in humans is still subject to controversy and investigation and may have far-ranging implications (Schiller and Phelps 2011; Nader and Einarsson 2010). During the short period of reconsolidation, suspected to last

for a couple of hours, memories become open for alterations and seem to be "updated" in light of present knowledge. Reconsolidation might imply that the best recollection we have of a past event is our latest recollection of it (and not the original perception which may have been "overwritten" by the altered memory). As a consequence, our memories are alterable without our awareness. Memory is not, as the ancient metaphor of a wax tablet or modern variants of a computer storage device suggest, a replication or a copy of the initially encoded stimuli but a repeatedly reconstructive process and thereby susceptible to alterations and contaminations. A remarkable fact, because from our subjective experience, we are (too) confident that memory is more of a replay of recorded information than an active, potentially error-prone process.

Whoever speaks about remembering should not forget forgetting, an equally interesting and important process. Already its definition presents problems. As not every transient inability to recall (such as tip-of-the-tongue inhibitions) amounts to forgetting, how do we know, as Nietzsche pondered, whether we ever forget? Smells, sounds, or sights can trigger quite powerful memories which were irretrievable in the absence of such cues. Strictly speaking it can never be ruled out that some regularly inaccessible memory traces, excitable under the right conditions, still remain (Cf. Roediger III et al. 2010). Like remembering, forgetting is a multifaceted phenomenon for which no unified theory exists. It can have various causes: faulty initial consolidation, retroactive interference, trace decay over time, or simple retrieval inhibitions (Wixted 2004; Schacter 2002).

In any case, forgetting should not be conceived of as cognitive defect only. It is instrumentally useful for thinking – and possibly even remembering – because it prevents informational overload by filtering pieces worth remembering. Without forgetting we may suffer the fate of Funes the Memorious, a fictional character by Luis Borges, who cannot forget and is completely observed in details (Borges et al. 2007). Patients resembling Fuentes and suffering from their hyperthymestic memory exist (Parker et al. 2006). William James once remarked: "Selection is the very keel on which our mental ship is built. And in this case of memory its utility is obvious. If we remembered everything, we should be on most occasions be as ill off as if we remembered nothing" (James 2007, p. 680). Even apart from cases of complete memorizers, accurate recall is not always beneficial. One does not need to subscribe to controversial Freudian notions like repression or psychological defenses to acknowledge that too much of the past can burden the present.[1] Remembering all unpleasant or embarrassing moments is not conducive to well-being. Especially autobiographical memory seems to be selective. Attenuating or amplifying particular memories helps to maintain a coherent and positive self-image (Conway 2005). Reversely, goal-directed forgetting in the service of personal needs lets us see the past with misty eyes (Harris et al. 2010, p. 254). Remembering and forgetting are thus complementary processes and we should not overvalue one while depreciating the other.

[1]A contemporary review of repression theory; see Erdelyi (2006).

Interventions into Memory

We have to leave it here with this brief introduction to memory research and turn to what is relevant for normative purposes: interventions modulating memory. It goes without saying that our conscious powers over memory are limited. In recent years, several novel interventions have been studied that affect the fate of recently acquired memory traces and that might also afford altering more remote memories. Although most research is still in its infancy, the prospect that novel insights into the working of the memory systems and novel intervention techniques may allow to alter memories seems warranted in principle.[2] These are exciting times for memory researchers even though for safety and ethical reasons, many of the interventions studied in animals will never be carried out in humans.

Three main goals for interventions into memory are conceivable: enhancing memories through improving encoding and retrieval; diminishing memories through inhibiting recall, erasing traces, or attenuating emotional aspects; or changing contents of memories. Generally, interventions into memory are possible in all phases: before or during memory acquisition, consolidation, or recall – and, perhaps most interestingly, even after recall during reconsolidation. Moreover, case reports of patients with deficits in particular memory functions suggest that specific memory systems might be targeted individually.[3]

A growing body of research seeks to enhance memory by different means, mostly by improving information encoding or consolidation. A powerful natural way to enhance memory is emotional arousal which leads to increased release of stress hormones such as noradrenalin and cortisol that enhance encoding and consolidation but can interfere with retrieval (Joëls et al. 2011). Some common drugs have both memory enhancing and impairing effects, depending on the time of application: Benzodiazepines, for instance, impair memory anterogradely when taken before but enhance memory retrogradely when taken after encoding (presumably through reducing interference with later incoming information) (Beracochea 2006). The public debate on memory enhancement focuses mainly on pharmaceuticals, but most drugs currently in use in humans fail to exhibit overly impressive beneficial effects on memory (Repantis (2010a, b; Husain and Mehta 2011; Lynch et al. 2011). Several non-pharmacological memory enhancers have been demonstrated to be similarly or even more effective than drugs, e.g., nutritional supplements, physical exercise, sleep, mnemonic strategies, or brain stimulation.[4]

[2]There will be many obstacles, especially in targeting specific memories; see, e.g., Levy (2007), Ch. 5.

[3]The most famous patient is the recently deceased H.M., c.f. Corkin (2002).

[4]For a broad overview c.f. Dresler et al. 2012; for nutrition c.f. Smith et al. (2011), Nehlig (2010); for exercise c.f. Roig et al. (2013), Hötting and Röder (2013); for sleep c.f. Rasch and Born (2013), Genzel et al. (2014); for mnemonics c.f. Karpicke and Roediger (2008), Worthen and Hunt (2010); for brain stimulation c.f. Coffman et al. (2014), Suthana and Fried (2014).

Different strategies exist for diminishing memories. Forgetting is the often unintended but natural fate of most memories. There are some indications that intentional forgetting of selected memories might be possible, a phenomenon called “directed forgetting” (Geraerts and McNally 2008). For emotional memories like conditioned fear, unlearning procedures (i.e., fear extinction) have long been established and have attracted renewed interest recently. Notably, however, most fear extinction procedures do not erase memory traces but merely inhibit recall through a newly learned safety memory (Myers and Davis 2007; Vervliet et al. 2013).

A primary target for interventions are emotions that accompany memories, particularly painful and stressful emotions related to memories of traumatic events. In most persons who have experienced trauma, the emotional tone of the memory with time disconnects from the factual memory, a process in which sleep plays a crucial role (Walker and van der Helm 2009). Some persons, however, develop post-traumatic stress disorder (PTSD), a pathological condition characterized by anxiety, easily recurring and hard to suppress memories of traumatic events, flashbacks, emotional numbing, or hyperarousal, as well as behavioral changes such as evasion of particular people or places.[5] The powerful and persistent memories are caused by stress hormones released during the traumatic event which lead to an overconsolidation of memory traces (Pitman 1989; Glannon 2006). Most therapies aim to blunt the strong emotions associated with the factual content of the memory. However, insofar as the original memory trace is not replaced but only its recall inhibited, relapse is a common problem (Vervliet et al. 2013). Novel interventions might open new routes for prevention and treatment of PTSD. Substances could be administered to persons before they will be exposed to potentially traumatic situations (rescue workers) or immediately after they have experienced, e.g., sexual assault; or in therapeutic settings during reconsolidation of reactivated traumatic memories (President’s Council on Bioethics 2003; Donovan 2010; Poundja et al. 2012; Schiller et al. 2010). Consolidation and reconsolidation of emotional memories have been successfully targeted with the β-adrenergic blocker propranolol (Cahill et al. 1994; Kindt et al. 2009). In pilot studies, tampering with (re)consolidation processes has successfully reduced PTSD symptoms, but larger studies have yet to replicate these effects (Pitman et al. 2002; Vaiva et al. 2003; meta-analysis by Lonergan et al. 2013). Whether these interventions only diminish emotional aspects or affect factual recall is unclear at present.[6]

[5]For the biological side of PTSD, see Pitman et al. (2012).

[6]Some researchers speak of “erasing emotional memories” by which they mean erasure of the emotional aspect only, while ethicists often speak indiscriminately of “blunting” of painful memories. These conceptual ambiguities might lead to misunderstandings and depend on the conception of memory traces. Cf. Holmes et al. (2010). For present purposes, it is only important that emotional and factual contents could, at least to some degree, be targeted and modified independently from each other.

The strongest form of memory manipulation is complete memory erasure. The first point for intervention is blocking initial consolidation to prevent information in short-term memory from being stabilized and transferred into long-term memory. It is also possible to intervene at later stages: During the labile phase upon recall, reconsolidation could be impaired or prevented (Pitman 2011; Parsons and Ressler 2013). In animal studies, blockade of both consolidation and reconsolidation has been repeatedly demonstrated by inhibiting protein synthesis in memory-related brain regions (Dudai 1996; McGaugh 2000; Nader at al. 2000; Alberini et al. 2006; Shema et al. 2007; Sacktor 2008). In humans, reconsolidation of episodic memory has been disrupted, e.g., through emotionally aversive stimuli or electroconvulsive therapy applied immediately after retrieval (Strange et al. 2010, Kroes et al. 2014).[7]

Another form of intervention changes contents of memories. The process of selective consolidation of a fraction of our experience and the repeated reconsolidation of these memory traces suggests that our memories may be less veridical than we expect. This intriguing view is backed by a long line of false memory research, most notably by Elizabeth Loftus, in which the content of memories could be altered or new memories implanted through various and quite simple means such as telling false stories about the past or suggestive questioning (Loftus 2003; Brainerd and Reyna 2005). In animal studies, false memories were implanted through sophisticated optogenetic interventions at the molecular level (Ramirez et al. 2013). The extent to which our memories deviate from our original experience cannot be reliably estimated at present, both in terms of false parts within a (by and large) correct memory and the overall amount of false memories. In general, the possibility of false memories is not the same as proving that many are indeed false. Supposedly, humans are capable of remembering many things correctly. Otherwise, the preservation of our memory system through natural selection appears unlikely (Schacter 1995, p. 25). However, Loftus' studies demonstrate that distrust in memory is warranted and that we can never be sure whether our recollections are correct – regardless of how vivid and familiar they appear to us. These findings have legal implications, especially for evaluation of eyewitness testimony and interrogative procedures (Schacter and Loftus 2013; British Psychological Society 2008; Nadel and Sinnott-Armstrong 2012).

Ethics of Memory

The ethics of memory is a fascinating topic that has received little attention yet (Cf. Blustein 2008; Margalit 2002). How should we remember – what, whom, and

[7]The current state of research in humans is less consistent than in animals, partly due to the complexity of interactions between different memory systems during reconsolidation; for a review c.f. Schiller and Phelps (2011).

in which way? How often and intense should we, for instance, reminisce about late family members? To whom do we owe duties of remembrance, to ourselves or the person remembered? Should we try to forget particular persons or events or, by contrast, struggle against the natural decay of memories by fabricating cues and records? All these questions converge to the more general one: To which degree should the past influence the present? Answers have to take our limited powers over memory into account. But in a time when technologies may confer more control over remembering and forgetting and turn them into matters of choice, ethics of memory becomes an important issue.

The prospect of manipulating memory beyond our natural abilities has sparked the imagination of authors and artists from antiquity to modern days.[8] Although different interventions raise different questions and deserve detailed treatment on their own, some ethical worries apply to all of them (we loosely speak of "altering" memories). On the level of the individual, two ideas pull into opposite directions: For one, historical truthfulness speaks in favor of maintaining accurate recollections of the past. It finds support in prominent ethical ideas such as the ancient "know thyself." By contrast, well-being and the pursuit of happiness may favor altering memories – even forgetting unpleasant ones – over accurateness. In both cases, memory serves as an instrument for cherished but potentially conflicting ethical ideals.

A good example of the first position is formulated by the US President's Council of Bioethics in its report "Beyond Therapy." It presents a balanced overview of potential benefits and pitfalls of memory alterations and placed the topic on the scholarly agenda. It has nonetheless attracted much criticism for its bioconservative stance and its (rather suggestive) conclusions. The Council expresses deep concerns over any form of memory alteration, including interventions that numb traumatic memories of PTSD patients: "Our memories make us who we are. By 'rewriting' memories pharmacologically we might succeed in easing real suffering at the risk of falsifying our perception of the world and undermining our true identify" (p. 227).[9]

Remembering Fitly and Truly

As an ethical standard, the Council suggests "remembering fitly and truly" (p. 228), unfortunately without stating more clearly what "fitly and truly" means, what it implies or in which relation both criteria stand. "Fitly and truly" is presumably best understood as remembering appropriately and accurately and rules out falsifying,

[8]Cf. movies like Eternal Sunshine of the Spotless Mind.

[9]Cf. Parens (2010) who reads the Council as not being opposed to PTSD treatment.

forgetting, or dampening memories. Prima facie, this appears to be an agreeable position. But let us explore it a bit deeper. Any obligation to remember accurately faces the problem that human memory is selective and distortive. Emphasizing accurateness would oblige us to rehearse memories that tend to be forgotten and dissuade us from romanticizing or glorifying the past. Consequently, interventions that improve true recall and diminish distortive effects should be endorsed. This, however, stands in some contrast to the spirit of the report, critical of any technological alteration of natural human abilities.

Eric Parens usefully suggests understanding "remembering fitly" in the following way: The intensity of memories and accompanying emotions have to stand in some relation to the magnitude of the event that caused them (Parens 2010). This criterion brings us some way in clearly disproportional cases. However, assessing the significance of events as well as adequate (emotional) responses is itself a value judgment in need of further criteria. What, for instance, is the appropriate response to the death of a friend, the breakup of intimate relationships, or embarrassing experiences? Hard to tell. And by whose standards? (Cf. Henry et al. 2007, p. 17) This is particularly important in regard to reactions to traumatic memories such as deep prolonged sadness and loss of trust or interest in mundane things. These might be quite appropriate responses to preceding events such as having gone through war or being sexually assaulted. In fact, how could we simply revert back to normality and enjoy life's pleasures after living through such experiences? Even if affected persons were haunted by memories for years, their reaction is not evidently disproportionate to the magnitude of the event. The problem with traumatic memories is not so much that they are inappropriate to the past but that they may lead to a dysfunctional life in the future. "Fit" and "functional," though closely related, have different reference points: appropriate vis-à-vis the past or a flourishing life in the future.

This leads us to the third ethical ideal which a US American Council cannot but recognize: the pursuit of happiness. The Council contends that remembering fitly and truly is a precondition for living a flourishing life. But this is dubious – at least, but not only – with respect to traumatic memories. The Council's argument heavily draws on the idea that there is something like "real happiness," different from feelings of pleasure, which requires coherence between the world and subjective feelings. Indeed, we should be skeptical about superficial happiness, gained only for the price of separation from reality and may (mis)appropriate Theodor Adorno's famous saying here that there is no real living in a false life. But albeit distrust against superficial false consciousness is warranted, it is hard to get around the fact that certain memories are debilitating which is not a desirable state and that memory alterations could assist overcoming inner obstacles grounded in the past. The resulting flourishing life might not be so "unreal" or "false" that it is not worth having. While the Council claims that happiness and remembering fitly and truly are parts of the same coin, we suspect they are different ideals that can come in conflict with each other. Out of this tension, the real challenge arises: Are we obliged to remember fitly and truly *even though* it impairs a flourishing life?

Identity

In the background of the argument stands the worry that memory alterations threaten identity. Indeed our autobiographical memories make us who we are. If taken away from us, we would be stripped from something fundamentally ours, deprived of some kind of access to ourselves – our autobiography. Nonetheless, the importance of every single memory should not be overstated. We all forget a myriad of things and events on natural ways without loosening our identity. Why should this be qualitatively different if we forget at will? Furthermore, a well-considered decision to erase memories might itself be an expression of one's personality.

Worries over identity are a common topic in bioethical debates. It has proven useful to differentiate between several meanings. The strongest form, diachronic identity, concerns the continual existence of a person, i.e., the conditions under which a person at one point in time can be reidentified as the very same person at a later point. In the wake of John Locke, some argue that autobiographical memory, experiential knowledge of one's past, is a necessary condition for personal persistence over time.[10] This implies that loss of autobiographical memory leads to a fissure in persistence: The new person is, in a strong sense, a different person, while the old one has vanished.[11] Accordingly, Alzheimer's patients suffering from irreversible memory loss would be numerically distinct from the persons that inhabited their bodies before onset of the disease. While the tragedy of dementia-related erosion of personality is indeed a striking example of memory's importance, it also points to a weakness of the memory criterion. Theory aside, we usually identify the old lady who cannot remember her past as our grandmother who raised us as kids and therefore feel (and are) obliged to care for her.

As any theory of diachronic identity has to allow for the ordinary degree of forgetting, interventions such as numbing or erasing particular memories will regularly not call it into question (although the Council suggests otherwise). Yet, a weaker sense of identity, closer to the colloquial use, might be affected: one's personality. Everyone has a past, and this past cannot be undone. If memories of our past make us who we are, changing our memories may change us. The question is whether altering our personality in this way is wrong. Essentialist thinkers urge that one should preserve rather than "betray" who one is. By contrast, existentialist-minded positions hold that we should be authors of our life, actively shaping our future in light of attractive self-images, even if that implies radical departure from former personality traits (Cf. Bublitz and Merkel 2009; Erler 2011). The wrongness of "betraying" who one *was* in the quest of creating a more desirable future version of oneself can hardly be found in claims of the former personality against its successors. Instead, it needs to be grounded in present interests of the person. In their pursuit, anyone attracted to

[10]In Locke (1979), he wrote of the "sameness of consciousness," traditionally understood as the memory criterion, but see, e.g., Strawson (2011).

[11]For more elaborated treatments on the relation between identity and memory, see Parfit (1984), DeGrazia (2005), Schechtman (2005), Galert and Hartmann (2007).

existentialist approaches may seek to alter the way she reacts to her past, including her memories, and concede historical untruthfulness for the sake of personal development. Abandoning parts of one's past is not tantamount to abandoning any personality, but altering it. Objections are thus convincing only if self-development is intrinsically wrong or if freeing oneself from one's past is counterproductive to that end. Given that many people seek to change the courses of their life and their way of being, often for the better, a wholesale rejection of self-creation appears implausible.

Self-Growth

Perhaps, shaping one's future through cutting links to one's past is doomed to failure. We take this to be primarily a psychological hypothesis. Without doubt, coming to terms with oneself and one's past is among life's major challenges. But might forgetting or editing memories not be part of it? Especially theories of "narrative identity" emphasize the constructive processes in personality formation. Persons compose stories about themselves, woven from various sources such as their recollections, beliefs, self-image, perception by others, and expectations and aspirations for the future (Cf. Galert and Hartmann 2007). Interestingly, studies suggest that persons tend to evaluate their past not truthfully but in ways conducive to well-being, by embellishing or depreciating it. Putting one's former self in a negative light might – just as downward social comparison – make one feel better about the present (Wilson and Ross 2001). Forgetting, selective remembering, and waning emotional reactions are thus to some degree ordinary processes that do not necessarily impair construing meaningful and functional narratives about oneself – they even seem to be regular features (Bell 2008). Then, truthfulness to the past might not be a central condition for self-development.[12] While this does not imply that editing memories is ethically advisable, it shows that it is not an insurmountable obstacle for self-development.

Nonetheless, those who cannot draw upon their history might indeed be bound to repeat it. This old wisdom seems to have a neuroscientific analogy: Findings suggest that persons with memory deficits also have difficulties in prospective planning because the same brain systems are involved in both tasks. Scientists speculate that the (evolutionary) aim of remembering is not accurate reproduction of the past but rather simulation of the future.[13] Be this as it may, engaging with one's past can be extremely beneficial for personality development. It helps to understand where one comes from and enables learning from (unpleasant) experience and developing strategies to deal with stressful events and ordinary nuisances of life. Accordingly, when we lose our history, we lose opportunities for self-growth. This may even be true for

[12]Some memory disorders impair forming a sense of self, e.g., Klein et al. (2004).

[13]The "constructive nature of episodic memory is attributable, at least in part, to the role of the episodic system in allowing us to mentally simulate our personal futures," Schacter and Addis (2007), p. 779, Schacter et al. (2007).

traumatic events which can acquire meaning in retrospect. Some traumatized persons experience "posttraumatic growth" and steer their life in novel directions (Calhoun and Tedeschi 2006). Blunting or erasing memories may block such developments. Yet, even though people give meaning to horrible events, it remains doubtful whether there is meaning to, e.g., being the victim of serious crimes. Presumably, giving meaning to tragedy is more a strategy for coping with emotional turmoil. Painful events should not be glorified because of potential positive side effects. Memory alterations could provide alternative ways of overcoming the shadows of the past and freeing up the inner resources that arduously working through trauma exhausts. But while therapeutic forgetting may have much to recommend, concerns that memory alterations could be used to overcome minor troubles and impair personal growth seem warranted, especially in light of notorious human traits such as impatience and discounting long-term drawbacks in favor of short-term benefits.

Finally, it should be reminded that even full memory erasure cannot ensure escaping one's past as long as others retain their recollections.[14] The fact that others know more about a person than she herself does can lead to bizarre and uncomfortable situations which might be worse than retaining the original memory. And we can learn from patients suffering from involuntary memory loss that many persons would feel urged to find out as much about their history as possible. Then, memory erasure would be self-contradictory.

After all, the question about the extent to which the past should influence the future touches upon an amalgam of potentially conflicting ethical ideals, none of which can claim strict priority. Remembering fitly and truly is neither conceptually nor empirically a necessary condition for a flourishing life. Corresponding normative demands may speak in favor of manipulating natural abilities which do not live up to those ethical ideals. Nonetheless, memory alterations pose various dangers, many uses appear imprudent and should be discouraged. In spite of this, there are potential benefits. In the end, much depends on the kind of memory altered, precise effects of interventions, as well as psychological and social consequences. These aspects cannot be determined a priori but have to be cautiously explored empirically.

Memory & the Law

The perspectives of law and ethics differ in important ways. The law does not provide answers about what is morally advisable to do. Unlike moral advice, legal provisions are binding for all. Neutral and pluralist democracies should not seek to impose on citizens contested views of a good life but enable the peaceful coexistence of diverging life plans. Specific legal provisions have to conform to higher level principles that give form to the structure of legal norms, primarily those deriving from constitutional and human rights law. Deeply entrenched in liberal

[14] In-depth discussions of further ethical aspects are Levy (2007) and Liao and Sandberg (2008).

rights is the idea that persons enjoy wide ranging autonomy in self-regarding matters, which entails the liberty to make imprudent and immoral decisions. The realm of legal freedoms is thus not coextensive with the morally good. Because of this, legal paternalism is highly contested, at least in theory (see, e.g., Feinberg 1986). In practice, most legal systems allow hard paternalism in order to prevent severe self-harm. Furthermore, legal rights are understood here as prima facie entitlements that have to be balanced against countervailing rights of others or legitimate public interests before final judgments can be made. Finally, since legal systems and cultures differ widely, the following has to remain on an abstract level and might not apply to every jurisdiction to the same degree.

In most countries, the use of memory-altering substances or tools is regulated by different legal provisions. Pharmaceuticals such as propranolol or antidementia drugs are scheduled substances which require prescription. Tools like brain stimulation devices fall under different regulations, while mnemonic training, physical exercise, meditation, or sleep are not regulated at all. Many provisions that restrict access to specific means are not enacted in virtue of their effects on memory but for other reasons. Current regulations based on means may thus appear incoherent sub specie memory and might be reexamined in view of present knowledge.

In general, only few legal provisions directly pertain to mental states. At least in theory, strong human rights such as freedom of conscience and thought place some parts of the mind outside the reach of governmental control.[15] Memory, however, is among the exceptions. States have always had legitimate interests in acquiring knowledge about the past. Every citizen can be summoned to testify as a witness and this may entail the duty to remember correctly.

Two rights are noteworthy: Mental health, a human right, e.g., under the European Convention of Human Rights,[16] affords citizens claims against states to refrain from actions that inflict mental harm and to protect them against such actions by private parties. Thereby it provides protection against infliction of memory disorders that amount to mental health problems. In addition, curbing access to effective (and relatively safe) treatments of mental disorders would interfere with the right to mental health. Consequently, it appears unlikely that courts would consider the promotion of ethical ideas such as truthfulness to one's past as sufficiently grave interests to justify, e.g., prolonged suffering from PTSD.

Moreover, some aspects of memory concern issues of identity and personhood and may therefore relate to human dignity.[17] For instance, retrograde amnesia or personality dissolving effects of advanced Alzheimer's can undermine dignity (make a dignified life almost impossible). Respect for dignity not only implies the obvious – a strict prohibition to contribute to severe memory loss – but might

[15]Art. 9 ECHR, Art. 18 Universal Declaration of Human Rights.

[16]Art. 8 ECHR, e.g., Bensaid v. UK, App.No: 44599/98, 6.5.2001.

[17]Although not always codified and subject to controversy, human dignity is often understood as the overarching principle of human rights law.

also oblige states to prevent the onset of these diseases, e.g., by providing access to antidementia treatment. However, the extent of positive obligations in general and to health care in particular varies greatly from country to country.

Freedom of Memory

Interventions into memory not directly related to dignity or health might not be adequately captured by current law. Defining novel, memory-specific regulations could soon become a challenge for lawmakers and legal theorists. As a starting point, Adam Kolber has proposed to acknowledge a novel right, "freedom of memory," which he describes as a "yet poorly defined bundle of rights to control what happens to our memories" (Kolber 2006, p. 1622; Kolber 2008). We concur with Kolber's proposal. Freedom of memory follows straightforwardly from the general presumption of liberty and is part of the special protection of the person, arguably the foundational concern of human rights law. In the following, we shall give some contours to the idea and sketch issues future scholarship has to address.

Scope of the Right

Right to Remember

Our strongest interest in memory is remembering our past, to preserve biographical events against sinking into oblivion. In virtue of its significance, it deserves heightened legal protection. On a basal level freedom of memory thus entails the right to remember.[18] It guarantees that persons are entitled to use their powers of memory at will. This right corresponds with a duty of others to refrain from interfering with memory. Interventions that impair memory such as electroconvulsive therapy or pharmaceuticals interfere with this right and require strong justification if administered without consent. We suggest, as a rule of thumb, that the right to remember is stronger – and more likely outweighs countervailing interests – the higher the relevance of particular memories or capacities for construing a meaningful and truthful life narrative.

In addition, the right has to protect accurate memories against distortive influences. Courts were confronted with this issue in repressed memories cases in the 1990s. According to some psychological theories, repressed traumatic childhood experiences can be recovered through explorative psychological procedures. Upon undergoing such treatments, some patients remembered that they were sexually abused as children and brought claims against ostensible perpetrators. These memories often turned out to be false. They were not recovered but (negligently) implanted by psychotherapists through suggestive techniques such as hypnosis, guided imagery, drugs, and positive feedback for reports of memories with abusive

[18]A right to remember does of course not entail a duty to remember.

content (Cf. Loftus and Ketcham 1996; Brainerd and Reyna 2005, Ch. 7). At times patients recalled bizarre events such as satanic ritual abuse and group rape. More astonishingly, even some alleged perpetrators confessed horrible crimes which they never committed, only because suggestive police interrogations implanted false memories.[19] For lack of reliability and scientific consensus, courts grew reluctant to admit evidence of repressed memories. Today, chances of conviction based on testimonies from recovered memories without further corroborative evidence are low.

These cases raised the question whether patients or the wrongly accused have causes of action against therapists. The patient–psychotherapist relation is subject to contract law; therapists have to provide treatment *de lege artis*, according to standards of medical practice, which were arguably not observed in these cases. At least, methods that potentially alter memory should, just as physical interventions into bodies, require informed consent. Patients have to be informed about the scientific status of the repressed memory paradigm and the risk of false memories. Implanting false memories may thus give rise to malpractice suits.

Moreover, the work of Loftus demonstrates that false memories can be implanted outside of psychotherapeutic contexts. To capture such cases, the law would have to establish noncontractual duties of care toward other persons' memories. The problematic point is that false information can suffice to distort memories, but as misinformation is virtually everywhere, it can by itself hardly warrant tort claims (Morgan et al. 2013). The law has to tailor more narrow duties for persons with special responsibilities such as interrogating police officers. Implanting memories not as innocuous as the one's used in research, e.g., having been lost in a mall as a kid, should suffice to ground tort claims (e.g., infliction of mental distress, a tort accepted in some but not all jurisdictions).[20]

Protection Against Erasure

Furthermore, the law should provide protection against unwanted memory erasure even when it does *not* lead to mental distress. Walter Glannon discusses a real case in point, here in a slightly modified form[21]: For removal of suspicious tissue, a patient has consented to local anesthesia and, if necessary, for full sedation. During surgery, the locally anesthetized patient overhears the pathologists diagnosing "bad cancer" and starts to panic. The doctor injects her propofol, sometimes called "milk of amnesia" because it induces short-term anterograde amnesia through blocking initial memory consolidation. After waking up, the doctor tells the patient the surgery has gone smoothly and reveals her devastating diagnosis in the following days.

---

[19]In a famous case, the accused confessed the murder of 25 infants after authorities pressured him to remember the events; cf. Levy (2007).

[20]A further question is whether third parties – the accused – can bring claims against therapist. In the landmark case Ramona v. Isabella, the court granted a wrongly accused father remedies; see Mullins (1996).

[21]Glannon (2010), 240f. The case is taken from TIME, Oct. 15th 2007.

This is a case of genuine memory erasure, but instead of causing distress the intervention temporarily relieves it. Similarly, perpetrators could erase memories of victims so that they are unable to identify them which could have the positive effect of preventing PTSD. Without causing mental distress, these interventions might not fall within the scope of currently accepted torts. In that case, tort law should be expanded to outlaw unwanted memory erasure regardless of its negative or positive consequences. Because of their importance, lawmakers may even consider to render the unwatend erasure of memories into a criminal offense (Bublitz and Merkel 2014). Of course, memory erasure might be justifiable in exceptional cases (arguably in the one discussed by Glannon).

Right to Enhance Memory

In the 1950s, Wilder Penfield pioneered experimental stimulation of the brain. Electrical stimulation of the temporal lobes evoked vivid memories of events long forgotten. At least, this is what patients reported. As those memories were never verified, they might have been mere fantasies (Schacter 1995, p. 12). However, more precise stimulation and better insights into memory traces could afford new ways to explore buried memories, and, so we suppose for the sake of argument, sufficiently veridical ones. Should persons have a right to undergo such procedures? Other means that potentially enhance memory such as the nontherapeutic use of antidementia drugs or mnemonic training raise structurally similar questions. Given widespread complaints about the fallibility of memory and the natural curiosity about one's past, a high demand for effective memory enhancements can be expected. As part of the struggle against episodes of one's life fading away and becoming irrecoverable, the use of enhancements falls within the scope of the right to remember. It is neither conceptually nor normatively confined to our limited natural powers of recall. It guarantees remembering as one pleases which implies a permission to employ memory-aiding tools. Restricting access to such tools interferes with the right.

Limits

These interferences could be justified. As a form of cognitive enhancement, memory-boosting tools face many of the ethical objections reviewed elsewhere in this volume. Apart from issues of safety, efficacy, and undesirable consequences of overly perfect memories, ethical and social concerns may justify limiting freedom of memory. However, in light of the importance of memory and the fact that our natural powers are limited – at times, tools may be the only way to acquire access to one's past – countervailing interests would have to meet a high threshold. Social interests strong enough to outweigh, e.g., the interest to remember significant events of one's life are hard to imagine.

Furthermore, restrictions of modern versions of the ancient *ars memoriae* such as mnemonic training seem hardly justifiable, although they may e.g., give a competitive edge in the job market. Access to pharmaceuticals can be regulated in virtue of side effects, but unless considerable negative effects on individuals or society at large are expected, doctors should be free to prescribe them. The liberty

to use memory enhancements becomes even stronger insofar as they have preventive effects against memory decay in the future.

In extraordinary cases, freedom of memory might find its limits in legitimate interests of others that some events be forgotten (Kolber 2006). Think about an offender's vivid memories of how he humiliated and abused a victim. Victims may have the understandable wish that these memories shall not persist. Yet, these memories may also be important for offenders (e.g., for coming to terms with their deeds). If means to erase particular memories become available, the law needs to strike balances between these interests. Apart from such extreme cases, the right to remember regularly prevails over social interests to forget.

Right to Forget

As memory is the interplay between recall and forgetting, the freedom of memory also entails the right to not remember and even to forget. Again, good ethical reasons may speak against intentional forgetting, but legal freedoms do not coincide with the realm of the morally advisable. Only severe self-harm can be prohibited on paternalistic grounds.

Not Being Reminded of Something

A right to forget entails that others do not have claims against the rightholder to remember. Therefore, the romantic promise of lovers to never forget a precious moment (and each other) cannot be understood as a binding and enforceable legal contract. Moreover, in our quest to forget, we try, to suppress thinking about particular persons or events. Often in vain, as we are inadvertently reminded of them by external audiovisual or olfactory cues. The right to forget cannot protect against being reminded as this would restrict other persons' freedoms, e.g., the right to speak about issues others are not pleased being reminded of. Only particular means of evoking memories in others can run afoul of freedom of memory such as unwanted electrical stimulation of the brain. Unlike speaking, no one is entitled to directly interfere with another person's brain. Even if such interventions were free of side effects, the elicitation of unwanted memories by itself violates freedom of memory. Between speech and brain stimulation lies a grey area of ways to stir up another person's memories, e.g., through placing cues in public places. But if elicitation of memories were sufficient ground for banning cues from the public, all kinds of stimuli would have to be removed. The public sphere, however, attended to by different persons with different sensitivities, must remain a place for free expression even if some take offense. A different conclusion might be warranted in special cases, such as a graffiti artist who intentionally places symbols that trigger traumatic memories in the social environment of abuse victims (such cases do exist). It is not the illegitimate appropriation of the public for personal purposes but the intentional elicitation of memories that can ground claims in those cases. In general, PTSD and stressful memories are a growing field of litigation, and the law seems more willing to accept such claims, providing some protection for peace of mind, although scope and limits remain to be worked out in detail (Shen 2012).

Intentional Forgetting

While freedom of memory cannot protect against exposure to any memory cue, it encompasses the right to forget through straightforward measures. Umberto Eco once pointed to an asymmetry between the *ars memoriae* and *ars oblivionalis* (Eco 1998). While we can establish associations and cues to remember, there is no analog method to forget. Although some indirect strategies to suppress unwanted memories exist (Anderson and Green 2001), forgetting is, by and large, not under our conscious control. The advent of consolidation-blocking substances could change this, and their use would fall under freedom of memory. But, just like any other freedom, it can be limited by countervailing interests.

Paternalistic Limits: Erasure of Autobiographical Memory

Let us briefly turn to one example of justifiable paternalism: complete erasure of autobiographical memory. It may sound like mockery to the ears of those who suffer from severe memory loss, but some persons may seek to completely eradicate their autobiographical memory. At present, there are no means to do so, but tragic examples of brain lesions prove that it is possible in principle. Suppose an intervention erases memory without impeding the capacity to store new information. In the great majority of cases, availing oneself of such means would be an imprudent decision that causes more harm than relief and states should step in. However, cases are conceivable in which even this radical memory modification appears as an understandable wish, all things considered, e.g., if tragic circumstances have come over the person which were not of her own making and severely obstruct a flourishing life in the future. To some, autobiographical memory erasure disrupts diachronic identity and it might be conceived as a minor form of suicide.[22] Countries that tolerate or assist suicide might, in order to prevent suicide, discuss regulations and procedures for such interventions, bizarre as they may appear at first glance.

Limits: Collective Memory

The tempting short-term relief provided by memory modifications might come at the price of negative long-term effects on personal development for which paternalistic restrictions seem warranted. We cannot delve deeper into this contentious issue here and shall turn to limits which derive from interests of the common good. A recurring theme in the debate concerns the effects of memory alterations on collective memory. The Council argues that "our own memory is not merely our own; it is part of the fabric of society in which we live" and pictures the social consequences of memory dampening by asking: "What kind of people would we be if we did not want to remember the Holocaust, if we sought to make the anguish simply go away?" (p. 231) The Council concedes that "we cannot and should not force those who live through great trauma to endure its painful memory *for the benefit of the rest of us*." Yet, rather

[22]The law would probably not accept changes in numerical identity and still consider the person as the same as she was before erasure of autobiographical memory with respect to, e.g., financial obligations. Whether persons can still be punished for crimes committed before is a more intricate question, see, e.g., Dufner (2013).

than concluding that victims should be free to forget painful events, the Council suggests that society should compassionately suffer with victims instead.

The Council worries that atrocities and outrageous crimes could simply be forgotten and that victims would no longer seek to redress injustice. In that case, we would indeed be morally bankrupt. However, if we listen to the stories of (traumatized) survivors, the assumption that they could have chosen to forget if they only had effective means at their disposal seems misplaced. On the contrary, many seem to have derived the strength to survive from what they conceived as their moral duty: to tell the world what has happened and to seek justice, in the name and in memoriam of those brutally murdered. The engraving on the Holocaust Museum, “for the dead and the living, we must bear witness,” seems to express a deep existential commitment rather than an externally imposed duty. In the Oath of Buchenwald, survivors declared “it was one thought that kept us alive: the time for revenge will come” and pledged to “take up the fight until the last culprit stands before the judges of the people.”[23] For many, forgetting has never been an option.[24] However, we shall refrain from speculating about personal motivations of survivors because atrocities might simply not be the right angle for framing general discussions of memory alterations. How to come to terms with singular historical catastrophes far exceeds present parameters, and such events may not lend themselves to generalizations. We suppose that one can unconditionally endorse the imperative to never forget the Holocaust but still argue about manipulating memory in minor cases. Those we shall have in mind in the following.

The Council contends that memories are not “merely our own”, not at one’s free disposal because they are part of collective memory, and, further, that forgetting or numbing could impair or render impossible fulfilling collective duties of remembrance. However, the contested, perhaps only metaphorically useful concept of collective memory seems to be misleading.[25] Individual memories are the sources from which communities weave the stories about their past. The construction of these social narratives parallels individual memories in interesting ways: It pursues goals, primarily strengthening collective identities, not necessarily historical truthfulness. Parts of history are embellished, others are left out; stories are retold and rearranged through cultural and commemorative events in the service of present interests. Accordingly, historians speak of memory distortions on the collective level, too (Schudson 1995). Normatively, however, the fact that individual memories are sources of collective remembrance does not make them “memories of the community,” nor do communities derive claims to access or preservation simply from the fact that they can utilize them. Arguments in this vein presuppose that

[23]Oath of Buchenwald, April 19, 1945.

[24]How to reconcile the duty toward memory with the need to forget is a central theme for Holocaust survivors; cf. the writings of Elie Wiesel, e.g., his Nobel lecture, Dec. 11, 1986 (www.nobelprize.org).

[25]See Ricoeur’s (2004), p. 120 discussion of Halbwachs’ ideas who coined the term collective memory.

individuals are obliged to contribute to forming collective identities and facilitating collective goals. This might be a moral duty, but not a legal one.

Regarding duties of remembrance, an ambiguity of the concept "remember" might be at play. Collectively remembering historical events is not the same as individuals reexperiencing the past. The former means, e.g., drawing lessons from history, paying tribute to involved persons, and commemorating the dead. It does not mean, by contrast, that the collective or any individual entertains an autonoetic, first-person memory. The collective duty is independent from, and can be fulfilled without, autobiographical recollections.[26] Because of this, collective memories of historical events can be kept alive even when all contemporary witnesses have passed away. Erasure of individuals' memories does not automatically affect collective memory. Surely, oral accounts of moral witnesses can support collective remembrance, and they may have a moral duty to testify. But if witnesses cannot, as the Council concedes, be compelled to painfully remember for the benefit of society, their testimony should be encouraged but ultimately left to their discretion.

Social Interests: Witness Testimony

In this regard, the law is stricter. Irrespective of painfulness, it imposes duties to remember on witnesses for the benefit of the common good, more precisely, for purposes of law enforcement.[27] In many jurisdictions, the failure of a summoned witness to testify accurately constitutes punishable offenses. The law has to rely on witnesses. For lack of other obtainable evidence, testimony plays an important part in various legal proceedings. Memory alterations could impair the accuracy of testimony, fact-finding, and the administration of justice. For reasons of a fair trial, testimonies have to be given before a judge or a jury and be called into question by all parties. This makes oral proceedings necessary. As they unavoidably commence some time after the incident in question, the law has to address the duties of witnesses and the legal status of their memories during the meantime.

While the legitimacy of the duty to testify is hardly disputed in principle – everyone has to contribute his share to maintaining a (just) legal order – its precise contours are less clear. Before court, witnesses have to testify to the best of their knowledge. However, if memories were erased beforehand, witnesses cannot but truthfully refer to their memory blanks. We are all too aware of the notorious memory gaps that strikingly often befall people as soon as they enter courtrooms (not all of them bona fide). Since memory blanks can be beneficial for witnesses, they might be tempted to bring them about, and other interested parties might offer incentives to do so. Already today, witnesses might be able to render their testimony useless for legal purpose by exposing memories to ordinary risks such as alcohol or repeated recall under distortive influences (or seek the help of false memory implanters). At least intentional memory

[26]The same can be said about worries to "make the anguish go away". Is it the anguish of the victim that shall persist or not rather the anguish of noninvolved persons, as an empathic response to the suffering.

[27]In special cases, procedural rules recognize painfulness of memories, e.g., in sex-related cases.

distortions contradict the duty to testify truthfully. As self-induced witness amnesia would seriously obstruct the administration of justice and cannot be tolerated by the law, memory alterations that undermine accurate testimonies should be prohibited. Insofar as current provisions do not capture self-induced memory loss, offenses such as destruction of or tampering with evidence should be extended to encompass engrams in the brain.[28] However, tampering with engrams is in many ways dissimilar to tampering with physical objects. Whereas the latter can be confiscated and stored, persons can, in view of the dynamic nature of memory, hardly be obliged to preserve unmodified memories (or the initial perception). Some modifications are inevitable as long as memories are recalled and reconsolidated. Thus the law should reconsider the scope of witnesses' duties of care towards their fragile memories in light of current research.

Memory blunting might be the most pressing issue. On the empirical side, the impact of emotional blunting on factual recall has to be investigated. If emotional responses can be numbed while facts are largely preserved, the main legal interest in memory – gaining knowledge about the past – is not seriously threatened.[29] If, by contrast, blunting deteriorates factual recall, delicate balances have to be struck between societal interests in preserving accurate memories and witnesses' right to mental health. Roughly, we suggest that persons not responsible for the event such as victims or bystander witnesses cannot be expected by law to suffer intense and debilitating trauma. The short time window for interventions during consolidation (a couple of hours) raises a host of practical problems that need to be addressed (Cf. Kolber 2006, p. 1587).[30] Eventually, after witnesses have testified, the law does not stipulate further claims over their memories.

Effects on Responsibility

Another objection pertains to the effects of memory alterations on moral responsibility. The Council voices the concern that the idea of moral responsibility could unravel because victims would not seek justice any longer: Instead of forgiving, they would simply forget.[31] From a legal perspective, this worry seems farfetched and reverses the interests in question. Among the major aims for holding persons responsible is redressing harms inflicted on victims. The victim's main claim is restoration of the status quo ante, i.e., to put him in a position as if the harming

[28]See Kolber (2006), p. 1589 for a US-specific argument to this end.

[29]On occasion, the law might have further interests in unmodified emotions (e.g., in assessing damages), Kolber (2006), p. 1592.

[30]Perhaps immediate, taped interrogations to record at least a first unaltered testimony should be developed. But even then some parties have a disadvantage as they cannot cross-examine the witness. Also, in the immediate aftermath it is impossible to predict who will develop trauma, so the interests to be balanced are unclear in the moment in which actions have to be taken. Furthermore, it is often not evident whether memories will be of legal relevance; how long should people wait?

[31]Ricoeur (2004) argues that forgiving can be facilitated through forgetting.

action had never occurred (restitutio in integrum). Because history cannot be undone, this claim often remains unfulfillable, and secondary (financial) remedies are awarded instead. Easing negative mental consequences for victims would be the closest approximation to full restoration. Mitigating psychological harm, if necessary through memory alterations, is therefore a demand of justice, not its abandonment.[32]

The sinister consequences memory numbing may have on responsibility are often illustrated by two powerful images: One is the soldier with subdued emotions, blind and unresponsive to the horrors in which he participates, an epitome of a soulless human killing machine. The other is borrowed from Shakespeare's Macbeth:

> Cure her of that: Canst thou not minister to a mind diseas'd; Pluck from the memory a rooted sorrow; Raze out the written troubles of the brain; And with some sweet oblivious antidote Cleanse the stuff'd bosom of that perilous stuff / Which weighs upon the heart?[33]

Memory & Conscience

The idea of people washing away their feelings of guilt along with their recollections or of murderers with a clean conscience is highly troublesome. Accordingly it is widely held that perpetrators of crimes should not, as Macbeth hoped for his wife, numb their pangs of conscience through memory-blunting drugs (Parens 2010). On a closer look, memory plays only an instrumental role in these cases. What is really at stake is whether persons are sometimes obliged to experience feelings of guilt. Moral intuitions suggest that a guilty mind should be a conscience-struck mind. But is this also a legal duty? This intriguing question falls within the ambit of another, firmly established human right: freedom of conscience, enshrined in every human right treaty and among the core guarantees of the human rights system. Judicature and scholarship consider the inner side, the so-called forum internum where conscientious beliefs and emotions are formed, as protected unconditionally, i.e., intrusions are strictly prohibited. The central idea is that the conscience of the individual must, in principle, remain outside of the reach of governments. Although the precise contours of the right and its limits have yet to be defined,[34] freedom of conscience seems to imply that states do not have any legal claim over the conscience of the individual and that regulations of substances cannot be grounded in undesirable effects on conscience. The social interest in sustaining pangs of conscience then appears insufficient to curb its freedom.

[32]Furthermore victims have moral claims against perpetrators, e.g., to explain their reasons for actions. Memory erasure could thwart these obligations, which are often not enforceable by law because defendants enjoy privileges against self-incrimination and can remain silent.

[33]Shakespeare, Macbeth, Act V, Scene 3.

[34]The best analysis is Hammer (2001).

However, one should recall that the notion behind the absolute nature of the right lies in the protection of the individual against persecution for deeply held moral convictions and pressure to renounce one's faith. The origins of the right date back to confessional wars in medieval times. Neither in its historical genesis nor in legal scholarship the possibility of intentionally silencing one's "inner guiding voice" of conscience has been thoroughly considered. It raises the deeper question whether liberal states can require citizens to possess a minimum set of socially desirable psychological traits. Can a legal duty to be a moral agent, potentially riddled by a guilty conscience, be imposed on citizens; might it be legally enforced through denial of access to conscience-numbing drugs or even involuntary enhancement of moral dispositions? Perhaps. These issues run much deeper than freedom of memory. Current interpretations of liberty of conscience prima facie speak against a legal duty to be struck by one's conscience.

Memories of Perpetrators

As a consequence, soldiers are not legally obliged to feel remorse and cannot, in virtue of this fact, be stopped from altering their conscience, but military codes of conduct could proscribe use of memory-impairing substances. In practice, however, the military likely encourages numbing if it lives up to the promise of reducing the high rates of personnel suffering from PTSD. We share worries of soldiers killing with a clean conscience and – although we acknowledge the general weakness of arguments based on human nature – cannot but agree that some valuable essence of what it means to be human might be lost in those cases. However, we also sense some hypocrisy in the contention that soldiers ought to bear painful trauma for what others have commanded them to do.[35]

The most convincing case for an exception to the absolute protection of conscience can be made with regard to culpable offenders. In an insightful analysis, Carter Snead shows that the various aims of criminal punishment in one way or another presuppose that offenders and society remember fitly and truly. Memory modifications may thwart these aims (Snead 2011). What follows from this? In general, offenders do not have to contribute to the aims of the criminal justice system. This point is particularly important with respect to rehabilitation, the reduction of criminogenic psychological factors to reintegrate offenders upon release, which is among the main penological aims. In many countries, offenders are entitled to access to rehabilitative support but cannot be coerced into participation. States may provide incentives and rewards (e.g., reduced sentence, therapy as a condition for parole), but offenders can ultimately refuse rehabilitative attempts to remold their minds and serve their full sentence instead (and may

[35]Kolber (2006), p. 1621 draws the parallel between physical and emotional wounds. If treating the former raises no worries, why the latter? We suspect because of an (implicit) intuition that soldiers deserve mental torments, which is unconvincing as a general principle.

remain in preventive custody subsequently).[36] Whether coerced rehabilitation is viewed favorably depends on one's stance on the legitimatory grounds for punishment. The venerable issue may attract renewed attention if novel means for rehabilitation prove effective. Perhaps states might deny access to substances that subdue emotions conducive to rehabilitation such as guilt, remorse, or shame as part of punishment. Nonetheless, we hasten to remind that offenders are entitled to basic rights such as mental health, including treatment of painful mental consequences which originate in their wrongful deeds. Thus borders between self-incurred (and morally deserved) mental turmoil and pathological trauma might have to be drawn. While working through and coming to terms with one's deeds should be the default position, in cases of severe PTSD symptoms, offenders' right to mental health seems to outweigh societal interests in their suffering and entitles them to therapeutic memory alterations.

A Duty to Enhance

Finally, Vedder and Klaming have proposed employing memory enhancements for the common good, e.g., to improve recollection of witnesses (Vedder and Klaming 2010). In their view, public interests in obtaining accurate testimony might outweigh freedom of memory of witnesses. Although for lack of reliable enhancers such calls are premature at present, it is worth pondering whether states could stipulate duties to enhance memory. Freedom of memory does not oppose voluntary but protects against mandatory enhancements. As argued before, duties of witnesses seem to end where (more than trivial) side effects begin. But even for apparently side-effect-free memory enhancements like regular sleep (Thorley 2013). or repeated retrieval of the respective memory (Chan and Lapaglia 2011; Pansky and Nemets 2012), a legal obligation might be considered an undue burden to witnesses. Further details depend on particularities of each jurisdiction. Some do not even require witnesses to "refresh" their memory, e.g., through consulting records, while others explicitly ban memory-altering tools, including enhancements.[37] If lawmakers are tempted to amend current provisions, more than side effects should be taken into account. Vedder and Klaming's proposal is intriguing because it prompts general considerations over the politics of memory.

Conclusion and Future Directions

For the most part of history, humankind's knowledge of the past has relied on orally transmitted accounts based on memories, individual and collective. Memory has been an extremely important capacity for cultural development, reflected in the

[36] Some countries have mandatory rehabilitation programs for drug users and sex offenders.
[37] Cf. § 136a German Code of Criminal Procedure.

fact that duties to remember can be found in the writings of many major religions (Margalit 2002). Forgetting has likewise been a tool for political power. Imperatives to erase names of disgraced persons can be found in the bible. A Roman punishment consisted in *damnatio memoriae*, the "condemnation of the memory" of a person. These were predecessors of notorious attempts to manipulate collective memory such as Stalinist retouching of historical photographs. Ricoeur points to the Edicts of Nantes by Henry IV whose very first article proclaimed that "the memory of all things that have taken place" during preceding wars "remains extinguished and dormant as something that has not occurred" (Ricoeur 2004, p. 454). Back then, amnesia was prescribed to secure peace. Today we can witness converse tendencies such as granting amnesty for people who truthfully testify before South Africa's Truth and Reconciliation Committee. Both examples prove the political dimension of memory.

Calls to employ enhancements for public interests should be viewed with suspicion. They would, for the first time, expand the reach of governmental powers over memory from external records directly into minds and brains. What if states enhance only those memories supportive of their cause – might the past not be alterable through partially enhancing recollection? What if other memories were subdued or erased? How could misuse of these powers be effectively ruled out?

The inaccessible nature of one's own and others' memories has shielded them from direct governmental access. Neuroscience might overcome these natural barriers with potentially far-ranging implications for the way society deals with memories of individuals and with history at large. They need to be discussed not only by ethicists but the general public and democratic institutions, in order to formulate a framework for a politics of memory. On occasion, the memories of a single individual have changed the course of history. This perspective might underscore the importance of freedom of memory and motivate its acceptance as a fundamental right. After all, as George Orwell urged, if governments acquire the means to alter the way we perceive the past, they may well acquire those to alter the future.

Cognitive Liberty or the International Human Right to Freedom of Thought

83

Christoph Bublitz

Contents

Abstract

The aim of the chapter is to draw attention to a fundamental right that is neglected in the law but that is highly relevant for neuroethics: cognitive liberty or freedom of thought. Although an internationally accepted human right, it has not gained practical legal importance. However, any regulation of neurotechnologies has to be evaluated in its light. As the right is unfamiliar to policy makers and even to many lawyers and legal scholars, its historical development and the main arguments for its recognition are sketched. Furthermore, some suggestions for its

interpretation, scope, and contours are forwarded and remaining open questions identified. According to international human rights law, the right is of absolute nature so that interferences cannot be justified for interests of the common good or paternalistic reasons. Whether this strict prohibition of intervening into other persons' minds can and should be sustained even in light of putative pressing public interests and various neuroethical considerations is one of the novel questions neuroscience poses for the law.

Introduction

"Thought is free" ranks among the prominent tenets of western philosophical and political thought, found in writings and speeches from Cicero and Shakespeare to solemn political proclamations. Freedom of thought is a big, influential, and, at the same time, an amorphous idea. It is not always evident what people mean when they allude to it. For one, it can describe a factual property of psychological entities called thoughts. "Thought is free" is then a statement that can be true or false, depending on the conditions of freedom and their realization, with freedom mainly pertaining to the independence of thoughts from constraints or determining causes. In a different sense, freedom of thought designates a normative claim, thoughts *shall* be free. As a right, it imposes duties on persons, primarily to refrain from interferences with thoughts and thinking processes of someone else. Freedom, in this normative sense, means that others do not have legal claims over thoughts of another person. The manifold statements praising freedom of thought do not often keep factual and normative meanings separate. At times, freedom of thought is even used interchangeably with nearby concepts such as freedom of speech. Of present interest is the normative sense: cognitive liberty as a political demand for liberty of thought. Still, it is worth pondering briefly over the first meaning too. What does the view that thought is free, widely held in commonsense psychology, mean?

Most of the time, we experience our thoughts as free, for instance, when we rather passively observe thoughts popping up and vanishing in our stream of consciousness. This phenomenological freedom seems to result from the absence of any felt causes or constraints of thoughts. Moreover, thinking is an activity, comprising a bundle of diverse mental capacities over which we have powers and conscious control to varying degrees. We possess some powers to direct our thoughts, e.g., when we deliberately set out to think about an issue or use our imagination. Although we do not normally think which thoughts we will entertain next – which would itself constitute a thought and would lead into an infinite regress – we can roughly steer the contents of subsequent thoughts and thus seem to think what we want and to be in control of our thoughts. At other times, by contrast, we cannot fully grasp our thoughts, suppress unwanted thoughts from circling through our heads, or stop the wandering of our mind. In those cases, control over thoughts is limited; hence, they might appear as "unfree." Apart from those and other (pathological) cases, the feeling of freedom of thought is an inescapable aspect of our everyday conscious experience.

In another sense, thoughts are free because of their private character. No one else knows the content of thoughts in the same way as the thinker does. Thoughts are not directly observable for others; they can only be inferred from verbal or behavioral expressions. In addition to this privileged epistemic access that confers authority over the knowledge of one's thoughts, privacy of thoughts can also mean that others cannot control our thoughts because they are inaccessible from the outside. It seems impossible to compel another person to entertain a particular thought or to implant ideas or opinions. One can speak to another person, irritate, annoy, or bombard her with all kinds of stimuli, but such interventions are so imprecise and indirect that they can be blocked by inner countermeasures in all but the most extreme cases. These characteristics of thought seem to roughly capture what is commonly meant by freedom of thought. They are nicely condensed in the lines of an old German folk song: *No scholar can map them/No hunter can trap them/No man can deny*: *Die Gedanken sind frei*! (*Thoughts are free*).

These properties of thoughts loosely map onto two forms of freedom that are typically distinguished: internal freedom as independence from inner causes or influencing factors such as emotions and external freedom as the absence of external forces that can monitor or alter thoughts. Some of the apparently familiar characteristics of thought just mentioned raise deep philosophical questions: In which way do we have privileged access to our thoughts – is thinking something like inner perception of mental objects? Can we sometimes err about our thoughts? Might not the external world determine the content of our thoughts? What is the relation between thought and thinker? And what are thoughts anyway? These questions already indicate that our intuitive idea of freedom of thought is in need of further exploration.

The picture of thoughts and the mind as an invincible realm of inner freedom, an inner citadel to which the world has no entrance, is in many ways questionable and misleading. It is deeply rooted in a Cartesian dualism of mind and matter. However, since the day's of Freud, psychology assumes to various degrees that thoughts are generated by a complex and largely unconscious psyche which apparently follows its own rules and dynamics. For instance, thoughts do not line up randomly but seem to stand in some relation to one another, yet we are often unable to introspectively identify the corresponding rule. Today, neuroscience approaches the workings of the mind via its material substrates on various levels, from the connectivity of brain networks down to molecular mechanisms. Irrespective of whether or not reductionist strategies will ever succeed in providing a complete explanation of mental phenomena including thoughts, the initially appealing idea of thoughts being independent from internal causes and influences cannot but appear as a naïve folk psychological belief, based on the transparent bounds of introspection that conceal the operations of the mind and brain from the inward gaze.

Furthermore, many psychological processes are not under direct conscious control. We cannot, e.g., alter our mood at will. Some types of thoughts, such as beliefs and opinions, are not free in the sense that we can bring them about

voluntarily because they adhere to rules of logic or semantics. And of course, many of our desires are not under our voluntary control either. Even those mental capacities that are consciously controllable such as reasoning, remembering, or calculating are limited nonetheless as they require depletable mental resources. Thus, although we have varying degrees of conscious control over our minds, including our thoughts, our internal freedom is limited in many ways.

Likewise, we may not enjoy a strong form of external freedom. Our thoughts are not sealed off from the outside world. Although thought control in the strict sense of directly controlling the content of another's thoughts is not (yet) possible, there are many indirect ways, from classic conditioning to psychoanalysis and cognitive therapy, that may can effectively change the way people think. The neurobiology of the brain has been targeted by more direct means since the days of crude forms of psychosurgery in the 1930s which proved that the mind is not out of reach of external forces.[1] At least since the pharmacological revolution of the 1950s, interventions aiming at altering mental states, capacities, and thoughts are widely employed by the state and psychiatry, not always based on consent of affected persons. While pharmaceuticals allow modulating some properties of thought such as speed or style of thinking, novel interventions afford targeting thoughts more specifically. Deep brain stimulation (DBS) may give a glimpse of the near future. In studies, stimulation altered recurrent obsessive-compulsive thoughts as well as thoughts related to depression and anorexia nervosa (Lipsman et al. 2013; Schlaepfer et al. 2007). Moreover, if the hypothesis of "concept cells," neurons that respond to particular concepts or ideas, proves correct, stimulation of particular neurons may enable to elicit specific thoughts (Quiroga 2012). Even though thought control is still far off, it seems that the degree to which thoughts can be accessed or altered through interventions on the biological level is merely a contingent matter.

Freedom of Thought

The advent of tools that confer more powers over our own and other's mental realm leads to the normative sense of freedom of thought. The question no longer is whether it is possible to change thoughts, but rather who should be allowed to do so, by which means, and for which purposes. In order to regulate novel mind-altering tools and to evaluate existing regulations, the law has to confront a fundamental question: What is the legal relation of a person to her mind? Which legal (and enforceable) claims do others, including the state, have over the mind of someone else? The topic is rarely addressed in this abstract way. Sometimes, it is couched in terms of "ownership" of minds, but in a strict sense, one cannot "own" one's mind in the same ways one can have – and sell or relinquish – property in external things.

[1]For the history of psychosurgery and electrical brain stimulation, see Valenstein 1974; Delgado 1969.

The relationship between a person and her mind is qualitatively different. After all, if our very existence is, as one may understand Descartes' "cogito" argument, predicated upon our thinking, what could be more constitutive of a person than her mind and mental states?

Advocates of cognitive liberty demand that the individual should enjoy a wide range of autonomy over what is on – and in – her mind. The term was coined by civil right activists of the Center for Cognitive Liberty and Ethics (CCLE). Their central vision has been elucidated in a series of programmatic papers by Richard Boire and Wrye Sententia (Boire 1999, 2000, 2001, 2005; Sententia 2004), in short: To secure "the right to control one's own consciousness [as] the quintessence of freedom."

Historical Glance

In the last decade, "cognitive liberty" has become a political slogan in support of various related causes such as the decriminalization of psychoactive substances or restrictions of involuntary interferences with other minds, from advertisement to coerced psychiatry. The underlying idea, however, is anything but new. Abstractly, it is best understood as the postulate that other persons – or the state – do not have claims over the contents of other persons' minds. Variations can be traced throughout the history of ideas. An early formulation is a maxim of Roman law: *cogitationis poenam nemo patitur*, no one shall be punished for his thoughts alone. It restricted punishable offences to outward behavior and liberated thoughts and opinions from the sovereign's control to some extent. In Christian theology, the freedom to (not) believe in the truth of scripture and the question whether force can and should be used to compel disbelievers to change purportedly errant beliefs were a recurrent theme since Augustine. In medieval times, competing ecclesial and worldly authorities delineated their jurisdictions and purviews of power such that the church took care of saving souls (so-called forum internum), whereas worldly authorities regulated external actions (forum externum). Thereby, the mind was placed outside the reach of worldly powers. It was one of the major goals (and achievements) of the Reformation to free the forum internum from ecclesial authority by proclaiming a direct connection between the conscience of man and God. Because God was held to rule directly through the individual's conscience, the mediating role of the church could be circumvented. The acceptance of freedom of belief and conscience and its exemption from access by authorities was a prerequisite of toleration, the basis to end religious strifes that rippled Europe for centuries. Historically, freedom of belief and conscience are conceived as the first human rights.[2]

Freedom of thought is, of course, the overarching motto of the Enlightenment, expanding freedom of belief to opinions on nonreligious matters. Kant famously

[2]For the history of freedom of thought up to the early twentieth century, see Bury 1952.

answered the question "what is enlightenment" with the claim that everyone ought to dare thinking for themselves. The demand of freedom of thought was a key element in the political struggles that paved the way for modern western democracies, and it was understood broadly as the uncensored exchange of ideas, freedom from persecutions for holding and voicing opinions, and freedom of expression and the press. Today, these freedoms are firmly established and well-defined guarantees of the human rights system and are protected by freedom of speech and expression which often entail the freedom to "hold opinions without interferences."[3]

Freedom of thought as such, however, has never received much attention although the mind has always been a central point of political, ideological, and social struggles. States always had an interest in mentally disciplining citizens. As Spinoza wrote, those rulers "exert the greatest power who reign in the hearts and minds of their subjects" and "were it as easy to control people's minds as to restrain their tongues, every sovereign would rule securely" (Spinoza 2007, p. 208). One of the first horrific examples of the extent to which the human mind can be forcefully bent was provided by Maoist thought-reform programs that successfully altered people's opinions through a mixture of deprivation, indoctrination, and sophisticated psychological means (Lifton 1989; Taylor 2006). The west responded to this communist "brainwashing" with research efforts, among others the infamous clandestine US MKUltra program which conducted experiments with mind-altering techniques, sometimes on unknowing subjects (Marks 1992; for behavioral modification Macklin 1981). Aware of the importance of neurobiology, psychologist William Sargant wrote about the ideological battle during the cold war that "the political-religious struggle for the mind of man may well be won by whoever becomes most conversant with the normal and abnormal functions of the brain and is readiest to make use of the knowledge gained" (Sargant 1997).

The International Human Right to Freedom of Thought

The importance of the mind has been reflected in human rights law. The freedom of the inner realm has been expanded from religious beliefs and conscience to thoughts in general. Article 18 of the Universal Declaration of Human Rights, adopted in 1948, explicitly guarantees that "everyone has the right to freedom of thought, conscience and religion." In an almost identical wording, it has been incorporated into almost every human rights treaty[4] and is thus a binding – and in

[3]Art. 19 Universal Declaration of Human Rights (UDHR); Art. 19-1 International Covenant on Civil and Political Rights (CCPR).

[4]Art. 18-1 CCRP; Art. 9-1 European Convention on Human Rights (ECHR); Art. 13 American Convention on Human Rights.

theory, effective – universal human right.[5] Many national constitutions, however, do not explicitly recognize such a right on the domestic level.[6] Reference to freedom of thought is nonetheless made sometimes in decisions of high courts. The US Supreme Court, for instance, held that freedom of thought "is the matrix, the indispensable condition, of nearly every other form of freedom. With rare aberrations a pervasive recognition of this truth can be traced in our history, political and legal."[7] These words sound as if freedom of thought was understood as a general principle of law. However, it is often not mentioned in cases prima facie affected by it. As an effective legal right, the appealing yet vague idea needs to be rendered more precise.

What does being entitled to think freely mean? Courts have never defined content and scope of the right in more detail. Even legal scholarship only provides some approximations. According to (nonbinding) commentaries of human rights treaties, it affords the "freedom to entertain any thought [or] moral conviction."[8] In combination with conscience and belief, freedom of thought "cover[s] all possible attitudes of the individual towards world and society"; it protects the "absolute character of the freedom of an inner state of mind"[9] and the liberty to "develop autonomously thoughts and conscience free from impermissible external influence" (Nowak 2005, p. 412). Accordingly, it prohibits being "subjected to treatment intended to change the process of thinking," "any form of compulsion to express thoughts [or] to change an opinion" (Vermeulen, supra, p. 752), or influence "of the conscious or subconscious mind with psychoactive drugs or other means of manipulation" (Nowak 2005, p. 413). In short, freedom of thought provides protection against severe interventions into minds that aim at altering thoughts or thinking processes and thereby opposes the use of most novel neurotechnologies on non-consenting persons.

Some identify a more abstract principle underlying the right, a general restriction of state power in line with the right's historical genesis: "The inner world of the person lies outside the jurisdiction of the state" (Harris et al. 2009, p. 428). In other words, the state has, in principle, no claims over minds of citizens. Yet again, this principle is neither widely accepted nor openly contested in contemporary constitutional theory. The relation of governments to the minds of citizens is an underexplored issue at present. At least, freedom of thought seems to be the reason for an interesting feature of positive law: The law is generally reluctant to directly

[5] Cf. the General Comment No. 22 30.07.1993 by the UN Human Rights Committee.

[6] This touches upon the problem of the interplay between international human rights and domestic law. Whether and to which extent human rights are enforceable on the domestic level differs from treaty to treaty and country to country. In some states, human rights treaties prevail over domestic law; in others, they have to be incorporated into domestic law through special legislation; in still others, domestic law has to be interpreted in light of international treaties.

regulate minds. Only few, if any, legal provisions explicitly stipulate that persons ought (not) to be in a specific mind state. Instead of minds, the law regulates behavior by pre- or proscribing external actions.

Practical Irrelevance

While courts and scholars have often reiterated the importance of the right, it has not made much difference in legal proceedings. Freedom of thought may very well be the only human right without any real practical application. One can only speculate about the reasons. For one, the law is generally hesitant to deal with ostensibly intangible mental states, mainly because of issues of proof and causation. Roughly, the law entertains a dualistic protection of the person. While bodies enjoy strong protection and every constitution protects bodily integrity, one only rarely finds similar provisions for mental integrity. Compensation for mental distress is only awarded in extreme cases, many jurisdictions do not even recognize, e.g., a tort covering mental harms without corresponding physical injury.

Moreover, legal thinking appears still permeated by folk psychological intuitions and impressed by the view that thoughts are by their very nature invincible. In 1942, the US Supreme Court was convinced that "[f]reedom to think is absolute of its own nature; the most tyrannical government is powerless to control the inward workings of the mind."[10] It seems that not much has changed. The law might not have the manifold effective ways to change minds in plain view, and this could partly be due to the way in which worrisome interventions are described. Terms such as "thought control" or "mind-control" evoke sinister images of universally ostracized actions like brainwashing, but may not adequately capture, e.g., injections of mind-altering substances. Many interventions are imprecise in their effects so that it is hard to understand them as exerting "control" over thoughts.

Absolute Protection

The practical irrelevance of the right has another important reason: In most human rights treaties, freedom of thought enjoys *absolute* protection, for which interferences cannot be justified by any countervailing interest. Unlike regular rights which have to be balanced against rights of others or public interests, absolute rights trump other considerations. Human rights law recognizes only few absolute rights (e.g., prohibition of torture or degrading treatment) which evince the exalted standing of freedom of thought.[11] This importance, however, has a downside in practice which can be illustrated by coerced psychiatry. Obviously, forcible administration of

[10]Jones v. Opelika, 316 U.S. 584 (1942).

[11]Under the UDHR and the ICCPR, the right is even "non-derogable" in times of emergency.

psychoactive substances modulating thoughts and emotions is the kind of treatment that the right prohibits. Because of its absolute nature, interventions are not justifiable on any ground. In practice, however, freedom of thought is not even mentioned or elaborated upon in respective judgments. Instead, it is debated whether patients have a (restrictable) "right to be mentally ill" or "to refuse treatment." Treatments are mainly considered on the bodily level (side effects of medications), which puts the genuine mental effects out of focus. Thus, in face of practical necessities and arguably ethical duties to interfere with the inner realm of citizens in some cases, freedom of thought is simply not applied or construed so narrowly that measures are not conceived as infringements. Narrowing the scope of rights to avoid having to justify interferences is an old conjuring trick of lawyers, with the paradoxical effect that those rights that should command utmost respect are belittled and stripped of practical importance. This is not to contend that coerced treatments necessarily violate human rights, as some civil rights groups maintain. But one would expect sound arguments in view of such evident interferences, and their absence indicates that the absolute protection of the mind is an idea that stems from a time in which means to coercively alter thoughts were not available (or even conceivable) and that encounters deep ethical concerns once they become so, as there might be alluring reasons to employ them. As an alternative to degrading the right to a proclamation of symbolic nature, it seems preferable to cast doubts on the absolute protection and argue for well-defined exceptions while maintaining the strong protection in principle.

Altering One's Own Mind

As formulated today, cognitive liberty comprises another dimension: the right to alter one's own mind, not only by one's natural capacities but also with the help of neurotools from pharmaceuticals to brain stimulation. It is important to note that the current law does not outlaw particular mental states. There is no prohibition to be "high" or in any other altered state of consciousness, just as there is none to have criminal thoughts, deviant desires, or enhanced mental skills. However, some means to attain those states are prohibited by drug regulations outlawing the non-licensed use and possession of substances from classic street drugs like marijuana to potential neuroenhancers like methylphenidate. Details of regulations and criminalization vary from one country to the next, but international drug control treaties impose a ban on many substances in nonmedical contexts.[12] The idea that persons may have a legitimate interest in their use for nonmedical purposes does not play a role in current drug regulation. From a legal perspective, the debate over cognitive enhancement is thus not very different from the one about decriminalizing classic

[12]Cf. The list of psychotropic substances under International Control by the International Narcotics Control Board (www.incb.org).

recreational drugs. Both directly pertain to the question to which extent persons should be free to alter their minds for nonmedical purposes of their own liking.

At the moment, attaining some mental states is factually only possible by breaking the law. However, as the law does not prohibit altered mental states, persons have a right to be in those states. This right would be weighty if it derived from freedom of thought, but the point has not been thoroughly addressed so far and depends on the exact construal of the right. Historically, this dimension has not been part of the guarantee of the right. However, as commentators suggest, freedom of thought implies the freedom to "entertain any thought." A strong right to be in mental state X must prima facie entail the permission to use the pathways to arrive at or attain X (as long as interests of others are not affected). Then, freedom of thought entails the permission to use mind-altering substances. Although such arguments have not been accepted by courts (yet), much speaks in their favor.[13]

More generally, it is interesting to see how different ways to alter one's own mind fall under different regulations. Novel tools such as tDCS or TMS are not regulated at all (Maslen et al. 2013). Other mind-changing stimuli enjoy quite strong legal protection, e.g., as part of freedom of speech and expression. In a landmark case concerning pornography, the US Supreme Court even suggested that control of stimuli that enter minds could amount to mind control.[14] At least, compelling reasons are needed to justify why curbing one type of stimuli interferes with precious rights, whereas curbing others does not. In light of freedom of thought, one cannot but suspect an inconsistency here. Different means may warrant different treatment due to safety issues, but the same strong liberty interest for using of mind-altering tools would have to be conceded before one can assess whether it is outweighed by potential risks in particular cases.

After all, at least in theory, a strong human right protects persons against unwanted interventions into their minds. It arguably also entails a prima facie permission to make use of mind-altering tools. This right is, however, of little practical importance. Freedom of thought has failed to stand the test of practical applicability; it did not exert much influence on court cases or drug policy presumably because the idea is too vague and – due to its absolute nature – the right too strong to provide reasonable guidelines for solving practical cases.

Arguments for Cognitive Liberty

This gives rise to the challenge for the law – and for democratic societies – to draw the outer boundaries of the person in her mental aspects. Many substantive issues over scope and content of the right have to be clarified. To this end, some no longer sustainable assumptions, such as the idea that thoughts are factually invincible,

[13]For a moral argument to that end, see Husak (1992).

[14]Stanley v. Georgia – 394 U.S. 557 (1969).

have to be jettisoned. On the normative side, an absolute prohibition of any measure that interferes with thoughts and thinking processes appears unreasonable, at least if the right is, as suggested here, construed widely to encompass the use of mind-altering substances. Likewise, interventions that restore mental capacities in incompetent persons are at least not unreasonable and should not be prohibited across the board a priori. Rather, exceptions to the absolute protection have to be cautiously discussed and defined.

Moreover, some open questions about the scope of the right can be identified: Current law primarily covers some mental entities – thoughts and opinions. Should legal protection be confined to them (whatever they exactly are) or encompass others? Neurointerventions target, e.g., emotions such as pleasure and pain, motivation and anhedonia, mood in general, volition, and other psychological processes and properties that may not self-evidently qualify as thoughts, but which are so intimately intertwined with thoughts – if separable at all – that a strong protection of one without protection of the other does not appear meaningful. As the mind becomes accessible on the cerebral level, the law may need to provide an all encompassing protection – freedom of the mind. On the other hand, the same level of protection for all mental states might not account for their differences. Memory, for instance, seems to be a special case in its significance for both the individual and society.[15]

Historical Arguments

Furthermore, the importance of the right has to be assessed. This requires a deeper theoretical exploration of the reasons for and the limits to mental freedom. Many contemporary calls for employing neuroscience for public goals do not exhibit awareness of the fact that a governmental permission to alter the way people think or feel is, at least in the eyes of the law, a paradigm shift from regulating citizen's conduct to governing their minds. The mind of citizens is not just another target for governmental regulation. It is what makes persons who they are. That is why mind interventions are among the most intimate conceivable invasions of the person.

As the right is not accepted in many national legal systems, it is necessary to sketch some of the reason for its acceptance. A first step is to excavate the historical significance of the right and the distinction between regulating conduct and minds. It might be noteworthy that even in the conception of an (almost) absolutist sovereign in the work that stands at the inception of modern political philosophy, Thomas Hobbes' Leviathan, a distinction between the freedom of inner beliefs and outward confession was drawn. While states can demand public confession of adherence to official doctrine, citizens remain free to believe as they wish in their hearts. State powers are restricted to regulating external

[15]Cf. the chapter on memory alterations and the law in this volume.

actions (Hobbes 1996, p. 306). This idea can be found in the works of many prominent authors. In the Doctrine of Right, Immanuel Kant formulated the idea, concededly oversimplified here, that the role of the state is to secure reciprocal equal freedoms. The freedom of one person can interfere with another person's freedom only if their actions collide in the external world, e.g., because two persons claim access to the same space or resources. By contrast, whatever happens in the interior of a person's mind never restricts the freedom of anyone else. The purview of legitimate legal coercion is thus confined to the regulation of outward actions (Kant 1991, pp. 230, and 214).

In a similar vein, John Stuart Mill emphasized the special role of the mind. In "On Liberty," he wrote:

> [T]here is a sphere of action in which society, as distinguished from the individual, has, if any, only an indirect interest; comprehending all that portion of a person's life and conduct which affects only himself, or, if it also affects others, only with their [. . .] consent. When I say only himself, I mean directly, and in the first instance: for whatever affects himself, may affect others through himself [. . .]. [T]he appropriate region of human liberty . . . comprises, first, *the inward domain of consciousness*; demanding liberty of conscience, in the most comprehensive sense; liberty of thought and feeling; absolute freedom of opinion and sentiment on all subjects [. . .]. Secondly, the principle requires liberty of tastes and pursuits; of framing the plan of our life to suit our own character; of doing as we like, subject to such consequences as may follow; without impediment from our fellow-creatures, so long as what we do does not harm them even though they should think our conduct foolish, perverse, or wrong (Mill et al. 2003, pp. 82–83).

Mill claims that over self-regarding matters, individuals should decide for themselves. The characteristics of a person, her bodily and psychological properties and first of all, the inward domain of consciousness, are the realm which exclusively concern her. Therefore, society does not have claims over those traits, even if it strongly objects to them. Mill's argument relates to his harm principle. Restrictions of freedom are only permissible to avert harm to others. Yet by themselves and apart from deeds, thoughts or opinions cannot harm others. Kant and Mill both dismiss a legitimate right of others or the state over the content of a person's mind, i.e., governments do not have any jurisdiction over minds at all. Consequently, states can only restrict behavior, insofar as it interferes with others' rights or public interests. Of course, one may raise objections: Perhaps the role and corresponding powers of present-day welfare states are broader than securing negative liberties. In addition, thoughts, apart from deeds, may hurt others on occasion.[16] Yet even if one rejects Kantian and Millian ideas, the central point should be acknowledged: It is anything but self-evident why states should have any powers over minds at all.

[16]For example, pedophiliac thoughts as in the US case of Doe v. City of Lafayette, 377 F.3d 757 (2004).

Modern Arguments

Although not often explicitly addressed, the idea of cognitive liberty is deeply entrenched in principles of modern liberal constitutions. Among its defining and widely accepted characteristic is the idea of autonomy. Oftentimes, the scope of autonomy in law is wider than in ethics. Legal permissions do not coincide with what is ethically advisable; they guarantee freedom for supposedly wrong or bad decisions as long as rights of others are not affected. Currently, autonomy is primarily applied to issues regarding a person's body. In many jurisdictions, bodily self-determination reaches so far that even life-saving medical treatments have to be eschewed without consent of the person (or a proxy). Interestingly, one finds much less discussions of "mental autonomy." Of course, the idea of autonomy is not inherently bound to corporeal bodies or the physical part of persons, but rather a general principle of the allocation of decisional competence. The far-ranging autonomy in primarily self-regarding matters granted by the law must equally apply to the mind, including potentially self-harming conduct.

Some further legal arguments should be briefly noted. Together, the diverse human rights form a system of protection with the person and her most intimate characteristics in its center. Many civil liberties and social and political rights expand the protection of the person into the social sphere as they are considered necessary conditions for the development of the personality and a flourishing life. All the other freedoms lose their reference point if the core, the protection of life, liberty, and integrity of the person, is neglected. As the mind is among the most essential aspects of a person, the drafters of the Universal Declaration of Human Rights called freedom of thought "the basis and origin of all other rights" with "metaphysical significance."[17] Boire writes: "If freedom is to mean anything, it must mean that each person has an inviolable right to think for him or herself. It must mean, at a minimum, that each person is free to direct one's own consciousness; one's own underlying mental processes, and one's beliefs, opinions, and worldview. This is self-evident and axiomatic" (Boire 1999).

Freedom of thought stands behind other well-accepted human rights which could be severely undermined without its firm protection (Cf. Blitz 2010). Freedom of speech, for instance, is not merely the right to utter words, but to engage in critical discussions with adequate information. By protecting the uncensored exchange of ideas, the right secures the outer preconditions to form and revise opinions. The deeper reason why states sought and still seek to control information is that they seek to control ideas and opinions. Of course, the mental and neurobiological conditions of forming and revising opinions are at least equally worthy of protection. Because both rights share the same goal, a legal prohibition of governmental censure of ideas without a prohibition of tinkering with brains would be

[17]Rene Cassin, quoted from Scheinin 1992.

inconsistent. Prima facie, the strong protection of freedom of speech has to apply to freedom of thought at least to the same degree.

Moreover, the legal structure and the distribution of rights and responsibilities are modeled upon the idea of a freely deciding person. Apart from larger metaphysical issues of determinism and free will, free decisions presuppose that the preferences on which decisions are made have not been brought about through manipulative influences (above ordinary degrees). The legal system can only legitimately ascribe responsibility and liability for decisions if it simultaneously guarantees a basic level of freedom from unwanted interferences with the decision-making process. If the law treats persons as self-determined and holds them accountable for consequences of their mind states (in criminal and contract law, “meeting of the minds”), it has to grant them the legal powers of self-determination. Then, cognitive liberty is the “right to free will” because it protects the conditions of possibilities of “free” decisions and actions. In light of these considerations, cognitive liberty is not merely a political demand that one can approve or reject, but among the foundations on which liberal constitutional democracies are built. Legal systems seem to presuppose freedom of thought and are bound by reasons of inner consistency to openly recognize and embrace it.

Challenges

Interferences: Do Means Matter?

Once freedom of thought is at least in principle accepted, questions of its violations surface inevitably. As the foregoing shows, the intensity and effects of interventions have to be taken into account. In a sense, we change each other’s minds and brains all the time. Reading these words changes thoughts of the reader. Eric Kandel once remarked that the deeper aim of his lectures is to cause anatomical changes in the brains of his audience. Because minds and brains are constantly changing, often due to external stimuli, the law cannot simply stipulate a prohibition to alter them in the same way as it prohibits altering another person’s body. Rather, the law has to develop a framework of impermissible interventions based on both means and effects of interventions. Interventions that alter opinions, modify decisions, or severely undermine thinking capacities may run afoul of the core guarantee of freedom of thought, whereas minor interventions might not necessarily do so. Boundaries have to be defined more concretely. What about, e.g., subtle shifts in cognitive processes or mood?

Further distinctions have to be drawn between different means to change minds. Whether neurotechnologies are in some way more worrisome than traditional means of altering minds is one of the deep philosophical questions raised by neuroscience. As it has manifold practical implications, it has already reached public discourse and the popular press. It stands in the background of

controversies such as whether children should be treated with methylphenidate or rather placed in better school environments, whether depression should be treated pharmacologically or through psychotherapy, etc. In these cases, the desired goal is often sufficiently clear, but the means to attain them is in dispute.

The issue is so controversial because it is inextricably linked to different worldviews and ideologies. In the 1960s and 1970s, the heyday of behaviorism and leftist movements, the external environment was conceived as the prime determinant of behavior and, e.g., mental disorder. As a consequence, social and economic conditions were conceived as the prime target for interventions. If, as Marxists would say, the social being determines consciousness, consciousness is best changed through changing the social environment. Alternatively, the psychoanalytic tradition identified the psychogenesis of the individual as the main factor and favored various psychoanalytic and psycho-developmental interventions. Then came genetics, and today, we witness a profound shift towards the individual's brain which is considered as potentially maladapted to the environment rather than vice versa. Thus, the brain appears as the most appropriate target of intervention. However, the reductionist view of humans, to some degree inherent to neuroscience, remains unbelievable for many people who thus eschew interventions on the neurobiological level and favor more holistic, spiritual, or natural ones. In short, different levels of explaining persons seem to suggest different means of intervening.

Even though the different explanations might not be as mutually exclusive as they appear at first glance, this metaphysical issue is far from being resolved in the near future. In the meantime, the debate should be freed from ideological parts by separating empirical from more principled questions. Any intervention has benefits and side effects. Whether a desired goal can be better achieved through one way or another is largely an empirical matter. Perhaps, side effects of pharmaceuticals do not outweigh benefits; perhaps, traditional ways have further beneficial effects such as promoting virtues as self-mastery and self-reliance. These are, by and large, empirical matters. The more principled differences remain apart from benefit and risk assessments. To some, neurointerventions are intrinsically worse because their effects take place on the cerebral level whereas others work more indirectly, because they are artificial and technological (as compared to supposedly natural alternatives), or because they alter personality traits and render persons "inauthentic." Such worries are widespread in the concerned public, and corresponding arguments deserve more attention than can be given here. For present purposes, it is necessary to discard crude dualistic assumptions and underline the presupposition that all interventions, from talk therapy to pharmaceuticals or brain stimulation, change the brain in some way. Under this premise, other objections appear as expressions of particular worldviews and thus ill-suited for matters of public policy. As a consequence, a widely held position in neuroethics claims that principled concerns over neurointerventions are unfounded and that means to alter minds are not intrinsically ethically different

and should be treated on par (again, risks and benefits of specific interventions notwithstanding).[18]

In a legal perspective, however, some means to change other minds are privileged. Consider again free speech. It entitles speakers to send particular stimuli, mainly those that qualify as communication because they convey opinions or information. When a speaker changes opinions of a listener, e.g., by a compelling argument, she may have altered thoughts, but not in a way which runs afoul of the idea of freedom of thought. By contrast, if the same effect was produced through a pill that alters opinions, the freedom to hold opinions without interference seems contravened. Individuals have a right against being subjected to unwanted brain stimulation but not necessarily against exposure to persuasive arguments. Consider state interventions with laudable aims. One can hardly deny that governments must possess some competency to influence the minds of citizens, e.g., for purposes of education. Many schools and universities are run by the state, and in the preamble of its constitution, UNESCO declares that "since wars begin in the minds of men, it is in the minds of men that the defences of peace must be constructed." Granting authorities a "teaching power" to instill important social values, such as peacefulness, seems justifiable – but not by any means (Cf. Tussman 1977). Compare a public campaign to foster law-abiding behavior by teaching the categorical imperative and raising awareness of the suffering caused by crime to a more advanced version of a recent study in which social norm compliance was improved by harmless electrostimulation of the lateral prefrontal cortex through transcranial direct current stimulation (tDCS). The authors conclude that their findings of enhanced "voluntary and sanction induced social norm compliance may be of relevance because noncompliance with social norms constitutes a major problem" (Ruff et al. 2013, p. 484). Assume for the sake of argument that main as well as side effects of interventions are relevantly similar – both change opinions and behavior in a pro-social way – should they be treated on par? If tDCS interventions were much cheaper, ceteris paribus, could or should the state require persons to wear stimulating devices instead of putting more effort in public awareness campaigns? Somewhere between these two approaches to promote norm compliance, the difference between Brave New World and a free – but morally conscientious – society seems to be situated.

Although many objections against neurotechnologies may turn out to be unsustainable, some normatively relevant differences between interventions remain. Among the most salient ones in above examples is that persons have more control over particular incoming stimuli such as words compared to electrical stimulation of the brain. The listener can think about propositions, rehearse, revise, or reject them; they enable her to form opinions. Even if the argument is so persuasive that it cannot but lead to a change of opinion, at least from the standpoint of a rational person, no harm has occurred since opinions and beliefs have to stand the test of counterargument. Abstractly, persons have more control over stimuli that

[18]Cf. the different version of the Parity Principle in Levy 2007.

are sensually perceived and enter conscious awareness because it allows them to engage with the contents. By contrast, stimuli that directly change brain activity on other routes and without (or only subsequently) evoking conscious phenomena are less controllable. Whether they are successful solely depends on their strength and biochemical properties of the brain. Stimuli that enter brains via our outward senses are processed by mechanisms whose function it is, by all their faults, to deal with them. To be effective, these stimuli have to engage with the other as a person and have to resonate with her personality, wishes, desires, and psychological properties. Brain stimulation or pharmaceuticals take different routes that circumvent these mechanisms and seem to treat the other more as a natural object. Whereas sensually perceived stimuli are regularly best considered as inputs into the cognitive machinery, direct interventions alter the machinery itself. Again, the difference does not lie in the false assumption that only some interventions cause cerebral changes, but rather in the fact that stimuli enter the brain via different routes and are processed by different mechanisms.

Are these differences normatively relevant?[19] This depends on the kind of duties persons have with respect to minds. If freedom of thought demands that we respect each other's mental sovereignty and forbids manipulating thinking processes, those stimuli that are informational inputs into the thinking machinery and appeal to reason fare much better than those that bypass control mechanism and alter the machinery more directly. Direct stimulation of the brain and persuasive arguments might be conceived as two poles in a broad spectrum of gradually different interventions which have to be carefully analyzed in light of a more fine-grained normative framework. As a first approximation, a concededly rough line can be drawn between interventions that intentionally bypass control capacities or exploit cognitive weaknesses on the one side and interventions that, at least in principle, respect control and freedom of thought as they do not undermine powers of resistance on the other. One example is subliminal messages entering minds through the senses without rising to conscious awareness. Because they are designed to bypass conscious control, they regularly do not respect freedom of thought of the receiver. Within the grey area that needs further analysis lie supraliminal stimuli which aim to change opinions by primarily appealing to emotions or other unconscious dispositions for which neuromarketing provides many examples. Traditional limits to marketing such as "misleading information" may not capture those subtle manipulative interferences which nonetheless appear worrisome in light of freedom of thought. Furthermore, external background conditions can be modified by placing stimuli such as scent, music, or odorless substances as oxytocin in locations like supermarkets to alter customer's behavior, e.g., raising their willingness to make purchases through increasing mood or lowering self-control. How society should deal with such lower-level, perhaps harmless yet potentially effective manipulations is a question that democratic lawmakers have to decide and which requires an open public debate informed by empirical findings.

---

[19] A more detailed argument against the Parity Principle can be found in Bublitz/Merkel 2014.

Paternalistic Limits: For the Good of the Person

Even if interferences are identified, the main challenge lies still ahead. Which interferences can be justified? In its current absolute interpretation, freedom of thought does not allow for any interference. Yet this understanding runs contrary to widespread practice and might be in need of reconsideration. Perhaps, narrowly defined exceptions are unavoidable. Rights are mainly limited for three reasons: for the good of the person herself, in the name of public interests, or because of rights of others. Whether and to what extent freedoms can be curbed for paternalistic reason, i.e., against the will of affected persons but for their own good, is a highly controversial question to which various legal systems provide different answers and which cannot be pursued in detail here. However, coerced psychiatric mind interventions as well as drug prohibitions constitute interferences with freedom of thought which – if justifiable at all – can only be grounded in a paternalistic rationale. As one cannot remain uncommitted on these issues without engaging with limits of paternalism, only some aspects shall be briefly mentioned. Psychiatric interventions often restore mental capacities and thereby increase *internal* freedom of thought but at the expense of freedom from unwanted external interventions. Thus, one dimension of freedom of thought has to be balanced against the other. Insofar as treatments are restricted to (legally) incompetent patients under narrow conditions and in pursuit of their best interests (rather than those of society, relatives, or medical institutions), weighty ethical reasons seem to speak in their favor and therewith for an exception to the absolute status of freedom of thought.

Prohibitions of pharmaceuticals and other tools to change one's own mind beyond therapeutic contexts face similar challenges. Freedom of thought prima facie permits their use, but without doubt, any reasonable drug policy must install restrictive measures. However – and a bit provocatively – if the idea of freedom of thought was taken seriously, the prime aims of regulation would consist in *enabling* persons to safely alter their minds to enhance their internal freedom. Such an approach would seek to develop a regulatory system with the least restrictive constraints and apt harm-reduction strategies (medical supervision, substitution, drug checking, etc.). Prohibition (and criminalization) would be means of last resort to prevent severe self-harm. This perspective would constitute a paradigm shift. The unquestioned premise of today's drug policies lies in the eradication of consumption at almost all costs. In some countries, the harsh political climate against mind-altering substances begins to soften, partly because of the work of NGOs such as the high-profile "Global Commission on Drugs" which called for an end on the "war on drugs" in an influential report in 2011[20] as well as scientists who urge an evidence-based drug policy (Nutt et al. 2007; Nutt 2012). But as these are complex political decisions touching upon many social interests, it suffices to say here that the right to alter one's mind is not adequately

[20]Global Commission on Drug Policy 2011.

acknowledged in current regulatory schemes.A better test case for paternalism regarding alterations of one's own mind is provided by a recent case report of a DBS treatment of a patient suffering from anxiety and obsessive-compulsive disorder. The electrodes were placed in the nucleus accumbens, a part of the "pleasure center" or "reward system" of the brain (Cf. Kringelbach and Berridge 2009). Stimulation of this area elevates mood, in correlation with the increase in voltage: The higher the voltage, the stronger the mood elevation, up to a point at which the patient reported to be overwhelmed by euphoric, drug-like sensations of happiness. Stimulation also modulates, e.g., motivation and feeling of relaxation. A level of stimulation was found which put the patient in a normal state. Usually, patients can alter the intensity of stimulation through a control pad, but when the pleasure-center is targeted, different devices are installed to prevent overstimulation. As only the physician has access to the parameters of the stimulation, the patient asked him to turn the voltage up because he would like to feel "a bit happier" during the next weeks. The request was denied because of the limited knowledge over long-term effects. Uncertain himself, the physician put the perplexing questions where "therapeutic levels of happiness" run and whether stimulation should be confined to those levels to the medical community.[21]

The case raises intriguing questions for the law. By regulating well-being, feelings of pleasure, relaxation, and motivational states, the simulation targets central characteristics of the person. Presumably, this is the most invasive, precise, and direct form of accessing important psychological properties of another person currently available. Who should have the power to control these aspects? Freedom of thought is implicated because elevation of mood and motivation also alter, as case reports show, the kind of thoughts that come to mind. Other rights could be involved. If the stimulation is controlled through an external device (or a remote control), increasing or decreasing pleasure or altering mood against the will of the person likely violates human dignity. The present case is less infringing because the patient has consented to stimulation and merely desires its modification. The physicians contend they "are clearly not obligated to change DBS parameter settings beyond established therapeutic levels just because the patient requested it." They are right insofar as they do not have to actively participate in the patient's quest to alter his mind. But what if he only demands surrender of the controlling device of (or, depending on the technical realization, the means of access to) his own brain? The level of happiness is so central to the person that any denial of self-determination requires tremendously important reasons. After all, one should recall, the historically first inalienable right was the one to life, liberty, and the pursuit of *happiness*.

The case is structurally interesting as it throws the problem of legal paternalism over minds into full relief. Already spatially, the transformation occurs exclusively within the brain of the person and all effects likewise transform the inward domain

[21]See the full case report in Synofzik et al. 2012.

of consciousness only. Society or others are affected, just as Mill argued, only indirectly through the person herself and thus lack claims over the level of happiness.[22] Curbing access must thus be based on paternalistic grounds. In face of unforeseeable consequences of unrestricted self-stimulation of the reward system, the physicians' cautious approach is commendable. This leads to the paradoxical point that even though the matter is highly intimate and normatively only self-regarding, it is equally dangerous and in need of regulation. This case strongly suggests that even hard paternalism in regard to one's own fundamental interests is warranted.

All three examples of paternalism hint at a deeper challenge for neuroethics. What the law requires – and often uncritically presupposes – is an ethical assessment of the desirability of particular mental states, properties, and capacities. Paternalistic restrictions can be justified only if they promote long-term interests of the person, all things considered. Such assessments have to rely on judgments over the (dis-)value of particular mental states such as artificially induced blissfulness, symptoms of mental disorders, or effects of specific drugs. Otherwise, risks and benefits cannot be reasonably compared. In the DBS case, physicians tried to predict long-term consequences of heightened levels of happiness, e.g., its effects on wants and motivation in an attempt to define a therapeutic (why not optimal?) level of happiness. Similarly, mind-altering substances are often conceived as producing "high" states, but what if one rather speaks about enabling associative or creative thinking? Or, suppose the contention that some psychoactive substances as LSD facilitate insights into one's personality and exploration of otherwise unattainable psychological depths proves correct – which dangers are worth taking for it? A framework to address such points is currently missing. Many ethical elaborations of various mind interventions are ultimately based on moral considerations rather than long-term interests of individuals. The law evaluates mental states without a sound basis and is in need of assistance from an ethics of conscious (and other) mental states.[23]

Limits Public Interests

Presumably, the most controversial issue is neurointerventions without consent for public interests. Freedom of thought, in its current interpretation, opposes any such intervention. In spite of this, every state resorts to them. For instance, psychiatric patients are also treated to avert harm to others, not only to themselves. Some countries deploy psychoactive drugs for interrogation ("truth serum") (Calkins 2010) or to render defendants competent to stand trial. The – at least to European

[22]This becomes self-evident if one imagines a person with identical characteristics bestowed upon her on natural ways. Then, others surely do not posses any claims over them. Prima facie the same must be true for electrically modulated mood.

[23]Cf. the call for an ethics of consciousness by Metzinger 2009, Chap. 9.

ears – most cynical form of involuntary treatment is restoring convicts' "competence to be executed." These interventions do not paternalistically advance interests of affected persons, but of the state or society at large.

Further applications of neurointerventions for the public good are proposed, e.g., neurosurgery of criminals or moral enhancement of potentially every citizen, enhancing mental capacities of eyewitnesses or impairing their ability to fabricate lies, and, most worrisome, military uses of neuroscience (Moreno 2012; Marks 2010).[24] To clarify, as long as individuals consent to treatments (under appropriate conditions),[25] their rights are not infringed upon; only involuntary interventions are in dispute. Of course, courts have recognized an interest against being subjected to such interventions in cases that came before them, but they often held public interests to prevail. Broadly speaking, governments and the public have inconceivably many interests in the minds of citizens, but by themselves, interests in curbing freedoms do not provide a justification for doing so. The absolute nature of the right opposes balancing freedom of thought with public interests. The question is whether this strict prohibition should be upheld. To put it in a slightly different perspective: If one were to follow the temper of the times and allow certain interventions for the public good, one would have to establish mental duties of affected persons. Everyone who has to undergo mind interventions by law must be under a respective enforceable duty. Such duties contravene the idea that others do not have claims over the content of one's mind. Where those duties originate from and where they end would have to be explicated, which leads into fundamental issues over the general kind of duties persons owe to each other and to the state. To those endorsing consequentialist premises, strict limits to governmental powers irrespective of consequences appear utterly mistaken. Nonetheless, especially human rights law is founded upon the conviction that certain parts of persons are inviolable and have to remain outside of governmental reach.

While this matter cannot be settled here and deserves profound inquiry, it should be reminded that imposing mental duties constitutes a paradigm shift with potentially far-ranging implications. Instead of taking persons as they are and restricting their external freedom, the state acquires claims over the person herself. Instead of governing conduct, states govern minds. Is this not opening Pandora's box? Is it not, in times of omnipresent security worries, only a small step to policing thoughts, enforcing mental obedience, drugging the dissident? Even if one were to accept an expansion of governmental powers into the mental realm, one principle of public law will remain: States have to choose the least restrictive measure in curbing liberties. Oftentimes, curbing external freedom is less infringing than intervening into minds as freedom of action weighs much less than freedom of thought.

[24]Cf. the chapter on moral enhancement in this volume.

[25]Cf. the paper by Shaw in this volume.

Finally, a different set of public concerns can be found in ethical debates. It might be summed up as the wish of many people worried about the pharmacologization of everyday life (or, as David Healy put it: birth, Ritalin, Prozac, Viagra, death) to live in a natural society that does not medicalize its problems. As such, even if embraced by a vast majority, this (understandable) wish over a societal atmosphere cannot overrule freedom of thought. However, freedom of thought might be invoked at certain instances to counteract some societal developments.

The Right to Use Versus The Right to Refuse

Mill and Kant argued that mental alterations fall outside the purview of legal regulation because apart from deeds, they do not harm others or do not curb other persons' freedoms, respectively. The debate over neuroenhancements demonstrates that these assumptions might be misleading (CF. Greely 2006; Merkel 2007). In a mental economy, economic surplus is generated mainly through cognitive labor. In a sense, this realizes an old Marxist ideal: The means of production belong to the workers. Yet as long as they compete in job markets, this does not lead to liberation, but produces new forms of pressure. Optimizing the brain through neuroenhancements is optimizing the means of production. Legally, freedom of thought implies the right to use enhancements but by the same token to refuse their use. Therefore, opponents such as transhumanists and bioconservatives can – and should – both embrace the right, only emphasizing different dimensions.[26] Although strictly speaking, no one is coerced to take enhancements simply because others do, factual pressures may become so strong that persons cannot refuse without taking severe negative burdens upon them. This social conflict primarily results from constitutions of minds, not actions, and the different interests have to be reconciled in some way by a democratic legislator. Thus, even though it might appear paradoxical at first glance, one of the strongest reasons to curb freedom of thought of potential users is freedom of thought of refusers.

Future Directions

The seductive idea that thought is free can no longer serve as a basis for the way the law deals with minds. Neurotechnologies that afford to modulate and manipulate cognitive and emotional processes raise manifold challenges for the law: The right to freedom of thought has to be acknowledged and interpreted in a way that lives up to its theoretical and historical significance. Scope, contours, and interferences have to be defined. The current legal overemphasis on the side of

[26]For a detailed argument why bioconservatives should embrace cognitive liberty, see Bublitz 2013.

the sender of stimuli through, e.g., strong protection of freedom of expression has to find its limits in cognitive liberty as the right to remain free from unwanted manipulative interferences. This could place novel boundaries even on some socially accepted interventions. Perhaps most importantly, the absolute nature of the right has to be called into question. Very important public interests may justify interferences. If exceptions were allowed, the state would acquire the power to impose mental duties by which governmental competencies were expanded from controlling behavior to governing minds. This is a dramatic shift that requires profound debate. Furthermore, the law tacitly relies on extralegal reasoning about the desirability of mental states for which neuroethics could provide valuable assistance. Which mental states should states promote, discourage, or even outlaw? In the end, the scope of freedom of thought defines the realm and limits of mental self-determination or the boundaries of social access to the mind. Answers to these questions will have far-ranging repercussions in many areas of the law as well as in social and private life.

Neuroimaging and Criminal Law

84

Reinhard Merkel

Contents

Abstract

Methods of neuroimaging have sporadically, though in recent years increasingly, occurred in legal proceedings. By now, however, it seems that they are about to enter courtrooms on a systematic basis. This poses a host of normative problems, to do, for instance, with future applications of neuroimaging to determine culpability, to test the veracity of testimony, or to predict the future dangerousness of perpetrators. The latter two, brain-based lie detection and “neuroprediction” of dangerousness, are examined in this chapter. Functional

DOI 10.1007/978-94-007-4707-4_165,

magnetic resonance imaging (fMRI) is taken as a paradigm model, and its potential impacts on criminal trials are explored. The analysis is premised on a range of basic distinctions: between (1) different phases of a criminal trial; (2) the divergent roles played by the parties to a trial, most notably prosecution and counsel, and the different evidentiary goals and burdens associated with these roles; and (3) between compulsory and consensual fMRI. It turns out that there are no good reasons to ban fMRI for lie detection or for neuroprediction from criminal proceedings entirely. Instead, it should be admitted differentially in criminal trials, viz., only for purposes of exoneration, but not of conviction, of the defendant. Substantiating arguments are expounded. In cases of preventive detention, it may even be obligatory for the state to offer chances of possibly exonerating brain imaging to perpetrators who were otherwise considered candidates for indefinite custody.

Introduction

Unless all indications are deceptive, we are at the brink of a more or less systematic introduction of various methods of neuroimaging into legal proceedings.[1] This pertains to all major areas of the law, public as well as civil and criminal law.[2] Here I will focus on criminal law and its normative foundations only. Indeed, it seems fair to say that, for a variety of reasons, none of the other legal spheres will be affected as profoundly and in a comparably vexing manner by the suggested development as the substantive and the procedural law of crimes. This needs no elaboration here. Suffice it to say that in criminal law the state deploys its sharpest sword, as it were, against its own citizens, and hence has a constitutional duty to meet the most stringent obligations to justify its measures. Broadly speaking, this is the main reason why any uncertainty concerning validity and reliability of methods of neuroimaging as well as its potential to intrude into protected spheres of its subjects is bound to cause greater irritations in the field of criminal law than in any other legal area.

Over the last decades, a whole range of brain imaging methods have been developed or, if already on hand, significantly enhanced. For the purposes of our analysis, their classification into structural and functional techniques is of particular interest. Those of the former type provide ways of demonstrating the anatomical status of the brain, whereas the latter make its activities (functioning) accessible to outside observers. Structural procedures are, for instance, CT (computed tomography) and MRI (magnet resonance imaging); functional methods are electroencephalography (EEG), positron emission tomography (PET), single-photon emission

[1]This, of course, is a very general and hence not very informative statement. Before it can be elaborated on, it needs to be differentiated into a host of distinctions pertaining to conceptual as well as factual and normative questions – matters which I will deal with in due course.

[2]Least so, presumably, to public law, for reasons not to be developed here. On the various potential applications in civil law (see Granacher 2012; Eggen and Laury 2012; Moriarty et al. 2013).

computed tomography (SPECT), and functional magnetic resonance imaging (fMRI). In what follows, I will concentrate on methods of fMRI. They are currently the most technically advanced and, in various respects, the most promising ways to explore brain functions. Hence, the normative problems of neuroimaging that we will focus on can best be expounded by examining this paradigm model.

I will not talk about the clinical merits of brain imaging, i.e., its diagnostic, therapeutic, and preventive values which are largely beyond dispute. Instead, I will investigate some of its nonclinical applications. All of them have long become objectives of extended research in basic as well as in applied sciences. But some of them have also entered the courtroom. That is what makes them normatively interesting in various respects, some of which appear to be new and unique.

Basic Science: Techniques

As indicated, magnetic resonance imaging (MRI) in its standard forms can be either structural or functional, depending on what it is destined to measure: anatomical structures of a brain or certain of its activities, viz., functions (Bigler et al. 2012). Structural images have their primary field of application in clinical contexts of diagnostic or therapeutic provenance.[3] More interesting for the purposes of criminal law as well as legal ethics is functional magnetic resonance imaging (fMRI). For according to the expectations commonly associated with its use, it is supposed to make observable to external examiners, though only in an indirect way, the neural correlates of certain mental processes in the minds of persons tested in a scanner while being engaged in various cognitive tasks or exposed to stimuli designed to evoke emotive reactions. And this is said to procure substantive ground from which the goings-on in subjects' minds become accessible (deducible) in some sense for outside observers. Sure enough, most of this wording amounts to claims that are much too sweeping. They require several conceptual and technical qualifications as well as normative *caveats*. We will turn to these later.

The physics and technical intricacies of fMRI are very complex, much more so than could be surmised by looking at what the media tell us about it, with their basic microphysical processes rooted in fundamentals of quantum mechanics. For our purposes here, we need not delve into such difficulties. The following sketchy account may suffice.[4] FMRI is an imaging technique that records certain "changes

[3]They do, of course, also have various applications in the law, e.g., in civil cases, such as medical malpractice suits where they might be used to demonstrate differences in structural brain conditions before and after an intervention, etc. Normatively, these are mostly trivial problems of no particular pertinence to imaging methods.

[4]For a brief yet still formidable description see Logothetis 2008; extensively Logothetis and Pfeuffer 2004; for overviews accessible to laypeople see Raichle 2009; Jones et al 2009; Langleben et al. 2012; Taylor 2012, pp. 103–110.

in the regional blood volume and flow that are associated with cognitive activity" (Langleben and Moriarty 2013). Oxygen consumption, glucose utilization, and therefore blood flow in the brain constantly change in ways that are closely and in a remarkably precise mode related to cellular activities in the respective neural areas (Raichle 2009, p. 118). Such cellular activities, in turn, are believed to be the substrate, and hence (in some sense) the physiological mirror, of mental processes of all kinds in the minds of subjects during their test in a scanner.

The data acquired in fMRI are based on differences in the magnetic properties of the content of blood vessels and surrounding tissues in the brain as well as on such differences between oxygenated (aortic) and deoxygenated (venous) blood. These differences are elicited and made measurable by exploiting differences in the "resonant" properties of subatomic particles (protons) of hydrogen atoms contained in the water molecules of brain cells and surrounding blood flows, namely, their varying capacities to resonate (i.e., to absorb and emit energy quanta) while being exposed to brief pulses of radiation. This is achieved by placing the head of the subject into a powerful magnetic field in the range of 0.5–5 T, generated and modified by the scanner, thus uniformly aligning all magnetic particles in the targeted brain areas, and then emitting large numbers of very brief consecutive radio waves which are also produced by the scanner. These pulses deflect the previously aligned magnetic axes of the hydrogen protons away from their state of collective equilibrium. Soon as a radio pulse stops, the protons return to their former equilibrium, thereby "resonating," i.e., emitting miniscule radio quanta that can be detected by the scanner. These signals vary in strength depending on which type of tissue the emitting protons belong to. Thus, they characterize the diverse organic matter from which they originate: oxygenated or deoxygenated blood or other tissue. It is these differential radiation echoes that the scanner records and processes in order to create its fMR images (cf. Matthews and Jezzard 2004).

The specific brain activity believed to be the substrate or (at least) correlate of certain mental activities is indicated chiefly by the varying "echoes" of either oxygenated or deoxygenated blood particles, hence the label these signals are commonly marked with: "blood oxygenation-level dependent" (BOLD). They are of particular interest to researchers or clinicians. BOLD imaging is presently the most widely used fMRI technique (Langleben and Moriarty 2013, p. 223).

The scanner also permits localizations of the collected signals in (brain) space, endowing the method with a high quality of spatial resolution.[5] By applying large quantities of radio pulses from different angles all around the head and recording

[5]Temporal resolution of fMRI is of necessity weaker since the physiological reactions of the brain to the various tasks presented to its bearer, i.e., the increased blood flow to its respective parts, take a few seconds time.

the diverse echo pulses thus elicited, huge amounts of data are collected by such successive measurement "slices" through the brain. The scanner further subdivides these slices into relevant units of volume, so-called voxels,[6] tiny cubicles of (currently) 1–3 mm per side. Data derived from the voxels can then be configurated by a computer program into 3D images of the brain. Subsequently, these images are colored differentially by the computer and projected onto a baseline picture of the individual brain, usually taken beforehand by a structural MRI. The colors used in this process accord to the varying quantities of blood flow indicated by the recorded BOLD signals. They have no inherent meaning and do not mirror a colorful reality in the brain. It is the researchers that (to some extent arbitrarily) specify what, i.e., which amount of differential neural activity, is expressed by each color. By convention, the general rule is that "the brighter the color (say yellow compared to orange) the greater the statistical significance of the differences between two conditions" (Jones et al. 2009).

It is important to note that these data do not depict any "absolute" measure of regional brain activity. Rather, what they indicate is "relative regional activity over time" during the test (Langleben and Moriarty 2013, p. 223). This is achieved by relying on a method called "cognitive subtraction" (Aguirre and D'Esposito 1999). Here is a brief expert description:

> This principle assumes that the fMRI signal difference between two behavioral conditions that are identical in all but a single variable is due to this variable. Therefore, a proper comparison (i.e., control) condition is critical for meaningful BOLD fMRI paradigm. The fMRI activation maps reported in the literature usually represent a statistical subtraction between the fMRI activity maps related to the target and control variables. Ideally, the comparison and target conditions would be identical, except for a single variable of interest (Langleben and Moriarty 2013, p. 223; see also Raichle 2009, p. 5).

Reliance on the "cognitive subtraction" method demands observance of elaborate criteria for highly sophisticated experimental designs on the part of the researchers if their endeavor is to be successful in terms of clinical relevance or meaningful in terms of basic science.

Metaphysical Problems of Mind and Brain?

This method, however, also accounts for quite another fundamental aspect of fMRI. Philosophers who have read their way through the vast literature on fMRI might wonder why there is never any mention, not even in passing, of the age-old metaphysical problem of the relationship between the mind and the brain. If one aspires to measure (albeit indirectly) the brain activity of a person in order to disclose certain mental processes in their minds, does that not imply that one adheres to a certain type of monistic materialism (or physicalism) in the said metaphysical debate, that is, to a position holding that all mental

[6] Derived from "volume element" in assonance with the two-dimensional visual unit "pixel."

events are either simply identical to ("nothing over and above") correlated processes in the brain or yet "supervene" on such processes and hence metaphysically depend on them? And is that simply to be taken for granted? In other words, aren't there any reputable dualisms around anymore in contemporary metaphysics?[7]

We may, however, leave this issue aside here as unresolved as it is in philosophy. The "cognitive subtraction" principle of fMRI makes sure that, irrespective of fundamental mind-brain metaphysics, fMRI scans are apt to deliver empirical results that can reasonably be taken as disclosures of relevant facts about the mind. For what they aim to determine is not some "absolute" mental state "in itself," plainly read off its neural substrate. That would certainly amount to a more magical type of science fiction. Rather, they only seek to establish a difference between two brain states by comparing two different patterns of brain activity. One of these is the "baseline" (or "control") state before the test person is confronted with a particular cognitive task, whereas the other is task related, i.e., induced by the particular variable in the experimental setting which is introduced by the test-specific performance. If a difference between the brain activation patterns of the baseline state and the task-related state consistently emerges while the subject performs a specific cognitive task, one can be reasonably sure that the variation in those mental states manifests itself somehow in the recorded difference in brain patterns and can thus be identified by the latter. Put another way, that the resulting "difference image" would represent only those neural areas concerned with the specific task of the particular test (Raichle 2009, p. 5). This is quite independent from whatever else the relation between mind and brain might be in terms of metaphysical monism, reductionism, dualism, supervenience, or even Cartesian causal interactionism. Hence, we can safely lay aside these unresolved problems of the philosophy of mind.

Neuroimaging of Deception: Feasibility? Admissibility?

As indicated above, our normative analysis has to start with some fundamental distinctions.

1. Firstly, one should keep apart the different purposes for which fMRI could possibly be utilized in criminal law procedures. Three of them are rather obvious

[7]For elaborated overviews on mind-brain identity theories, on supervenience and on dualism(s), see Stanford Encyclopedia of Philosophy, entries "Mind/Brain Identity Theory" (Smart 2013), "Supervenience" (McLaughlin and Bennett 2013), and "Dualism" (Robinson 2013). To be exact, supervenience theories, holding that mental processes are asymmetrically dependent on corresponding brain processes, are really a form of moderate dualism (albeit decisively different from all types of "substance dualism" in the wake of Descartes' classical position which has only few followers these days). Supervenience, of course, is perfectly compatible with the assumption that measuring certain brain processes via fMRI can disclose correlated mental events.

(albeit not exhaustive): lie detection, assessment of responsibility, and prediction of future dangerousness. In what follows, I will confine my analysis to the first and last of these issues, i.e., on neurodetection (of lies) and neuroprediction (of dangers).[8]

2. Secondly, the question whether fMRI is a sufficiently reliable method of evidence in criminal law and hence admissible in the respective legal proceedings should be distinguished from the normative question whether such applications can be justified in principle, which is to say, even if fMRI turned out to be a scientifically valid and reliable method of evidence. It is by no means clear ex ante which of the risks possibly posed by the use of neuroimaging in criminal law appears more alarming: that of their uselessness or of their potency for evidentiary purposes.
3. Thirdly, the different roles of the parties in criminal trials[9] associated with divergent, in part conflicting, interests must be taken into account. Not all of these roles are equally suited for an attempt to deploy neuroimaging methods for one's particular aims.
4. Furthermore, a criminal trial is not a homogenous process with one invariable objective (be it retribution, prevention, a mixture of both, or something else) remaining constant through all parts of the proceedings, and with immutable interests of the parties involved as well as of the state and the public. Rather, it consists of a number of distinct phases, each of which is assigned a different principal purpose by the law and in each of which the roles of the parties and of the witnessing public also change to varying degrees.
5. Finally, of particular importance here is the distinction between the trial procedures in court (criminal proceedings proper, as it were) and, as the case may be, the subsequent enforcement of a prison term. During the latter too, insights into the mental sphere of a prisoner, possibly procured by an fMRI, might well be of special importance, be it to the prisoner himself or to the state and the public, for instance, if such insights were apt to sustain a reasonable prediction about the future dangerousness of the prisoner after a potential discharge from jail.

All of the above distinctions are of a more or less rough-and-ready kind. But they must be taken into account as one reflects on the problems of fMRIs in criminal procedures. All of them are associated with varying kinds and degrees of significance that the results of a neurotechnical access to the mental sphere of a party, be it the defendant or a witness, might have for that party itself as well as for the others in

[8]The important issue of neuro-assessing guilt and responsibility would require a whole treatise of its own, presupposing a clarification of the concept of (criminal) responsibility, which in turn implies hotly contested issues of freedom of the will, including the "principle of alternative possibilities" (PAP) as an alleged prerequisite of free will and responsibility, and other perennial issues in the metaphysics of mind. I have developed my own thoughts on these topics elsewhere (cf. Merkel 2008, 2011).

[9]Mainly the accused and his or her counsel; the prosecutor, judges, and jury; witnesses and expert witnesses; and, to a limited extent, the victim of the tried criminal offence.

every phase of the process. Put in the sweeping form of whether or not neuroimaging is admissible to courts in criminal law, the question admits no sensible answer. So the following considerations will keep in line with the foregoing delineations.

Lie Detection in the Trial Phase: Validity? Reliability?

For quite some time, measurements of physiological indicators of deception, such as skin conductivity, blood pressure, respiration, and a few more, have been conducted by employing the traditional "polygraph" which measures activity in the peripheral nervous system to detect deception. Two different methods of acquiring the relevant data have been used: the "control question test" (CQT) and the "concealed information test" (CIT), or more popular "guilty knowledge test" (cf. MacLaren 2001). In the course of the former, usually three types of questions are posed to the test person: firstly, incriminatory ones (such as "Did you kill your wife?"); secondly, irrelevant and harmless control questions (such as "Who is the current president of the United States?"); and thirdly, control questions about nonspecific misconduct, designed to somehow strain even nondeceptive subjects, but not in an specifically inculpatory way, i.e., not with regard to the particular incident in question (such as "Have you ever mistreated your wife or your children?"). By contrast, the CIT takes aim at highly specific and crime-related knowledge that subjects could only possibly have if they were indeed involved in the perpetration of the criminal offence in question. If that is the case, their autonomic nervous system will respond differently from that of an innocent person to such interrogating stimuli. Or so it is claimed.

The polygraph has come into disrepute, at least with regard to its application in criminal cases. Most, though not all, courts in Europe as well as in the United States have disapproved polygraph-based evidence (cf. National Research Council 2003, Chaps. 3 and 4). This pertains particularly to its CQT version as opposed to the CIT. The latter method whose reliability appears to be significantly superior to that of CQT (Ben-Shakar and Elaad 2003, p. 132; MacLaren 2001) has also been extensively examined in correlation with fMRI (Hakun et al. 2008; Gamer et al. 2007, 2012). Insofar, some of the prospects for a scientifically valid forensic application expressed by competent researchers have a considerably more optimistic tone than the majority of voices dismissing the polygraph (Gamer et al. 2012, p. 513; Langleben et al. 2012; Langleben and Moriarty 2013; see also Vincent 2011). This is, however, vehemently contested terrain. Other scholars, by contrast, are no less concerned about fMRI applications in court than they are about polygraphy (Mobbs et al 2007). Some of them resolutely deny an admissibility of fMRI lie detection in court at least for the time being (Morse 2006, 2012; Greely and Illes 2007; Sinnott-Armstrong et al. 2008; Uttal 2009; Pustilnik 2009; Kanwisher 2009; Moriarty 2009; Brown and Murphy 2010; Oullier 2011; further references in Schauer 2010, pp. 1199–1202). Others even demand an outright regulatory ban on "any non-research use of new methods of lie detection, including specifically

fMRI-based lie detection, unless or until the method has been proven safe and effective to the satisfaction of a regulatory agency and has been vetted through the peer-reviewed scientific literature" (Greely and Illes op.cit. 413). Furthermore, to some extent, the controversy is reflected in a whole range of court decisions. Some of these have admitted fMRI in criminal proceedings (though mostly to no avail for the verdict), whereas (more) others have rejected it.[10] It appears impossible, at least for legal scholars, to take a fair, scientifically attestable and yet decisive stand on either one of the sides in this controversy.

There is, however, also no need to do so here in order to sensibly pursue the matter further. Most of the concerns voiced by skeptics relate to certain standards of scientific validity and reliability in expert testimony required for evidentiary purposes.[11] With regard to such standards, they find all currently available methods of fMRI for lie detection to be wanting in various respects. And from this perspective, a plausible prima facie case against fMRI lie detection can be made. Objections may invoke not only the technical difficulties of the scanning procedure or the intricate problems of developing effective test paradigms but also the complexity of the cognitive processes involved in the natural phenomenon to be investigated: human deceptive behavior.

Such behavior includes cognitive processes to generate intent and strategies of deception in a given context as well as executive processes to perform the chosen deceptive act (Luber et al. 2009). A useful, albeit still coarse, taxonomy distinguishes four categories of cognitive functions associated with deception: information management, risk management, impression management, and reputation management (Sip et al. 2007). Each of these activities itself encompasses a set of more elementary functions, such as planning, employing one's working memory, selecting between alternatives, and modulating response inhibition (Luber et al. 2007). All of these processes are assumed to interact in a systematic, though largely unconscious, way during deceptive behavior. Furthermore, in order to be accessible to fMRI investigations, this complex cognitive machinery must, at least roughly, be understood in terms of its neural underpinnings – a formidable task fraught with nescience and uncertainties. To cut this still extendable account somewhat short, if one simply assesses the potential of fMRI to disclose deception vis-à-vis such difficulties and against the backdrop of a universal standard of validity and reliability in natural sciences, the prospects for success certainly are rather bleak.

[10]Overviews in Jones and Shen 2012; Aronson 2010. Most noteworthy of these rulings perhaps the verdict in *Semrau* (US v. Semrau 2010; affirmed US Court of Appeals, 6th Cir. 2012; see also Gary Smith v. State of Maryland 2012). It is not only based on established juridical reasoning but also on an in-depth examination of the available scientific evidence from the perspective of evidentiary requirements in the criminal law.

[11]In science, "validity" and "reliability" are distinguished (though related); the former refers to whether research results really demonstrate what they purport to, whereas the latter to whether such results are consistently obtained in sufficiently equal experimental situations. In law, however, both terms are frequently used interchangeably. Nothing hinges on this terminology here; so in what follows, "validity" can usually also be read as "reliability," and vice versa.

There is, however, no such thing as a uniform, homogenous standard of scientific validity applying to all evidentiary purposes that are legitimately pursued by parties to criminal proceedings. This pertains especially to the three major players in court: the defendant, the prosecution, and the jurors or the judges. As is well known, the defendant, or his counsel, does not have to proof anything, neither his innocence nor truthfulness. Things are quite different from the perspective of prosecutors and, in the end, judges or juries. What stands in need of sound proof in criminal trials is every single precondition required for a guilty verdict: firstly, all relevant facts establishing that the deed in question was committed by the accused[12]; secondly, the absence of justifying circumstances, such as self-defense[13]; and finally, the preconditions of the defendant's personal culpability.[14] All of this must be established "beyond reasonable doubt" or (amounting to the same standard) "to the firm conviction of the court" by prosecutorial evidence. And none of its potential refutations falls on the part of the accused, not even to some weak standard of plausibility, let alone doubtlessness. On the other hand, he or she certainly has a right to proffer all sorts of possibly refuting evidence that might exonerate them. This decidedly asymmetric allocation of the burden of proof, a corollary of the fundamental principle of "*in dubio pro reo*" ("benefit of the doubt" for the suspect),[15] must have, one would surmise, some bearing on the question of standards of scientific validity that have to be met by the prosecution, on the one hand, and by the defendant, on the other, in their respective efforts to provide evidence for or against certain relevant circumstances.

Against this background, all a defendant needs to establish in order to evade conviction is some qualms in jurors' or judges' "firm" confidence in his guilt to the rather small degree that suffices to preclude the "beyond doubt" criterion. So he

[12]Which encompasses all objective facts constituting the commission of the offence ("actus reus") as well as the required subjective facts on the part of the defendant ("mens rea").

[13]Note that this absence of justifying circumstances is regularly *presumed* unless there are concrete indications to the contrary. In other words, the realization of the elements of crime of a particular offence, i.e., of a behavior that is *generally* forbidden on pain of punishment, indicates prima facie that it was also forbidden (unjustified) in the *concrete* case. So with regard to particular justifications, there is often no need to proof anything. But if there are indicia of the presence of justifying circumstances during the perpetration of the deed, the final burden of proof of their *absence* falls on the prosecutor.

[14]And, as the case may be, the absence of specific exculpatory circumstances. Not all legal orders contain provisions for such specific exculpations, but many do. For instance, according to Art. 17 of the German Criminal Code (GCC), an *inevitable* error on the defendant's part that his behavior is (or was) lawful exculpates him (but does not, of course, make the *deed* itself lawful); certain forms of non-justifying necessity (threats to life, bodily integrity, and personal freedom) also have this effect (Art. 35 GCC).

[15]Contained in various Human Rights Conventions in international law, e.g., Art. 6 para 2 of the European Convention of Human Rights (1950).

may well be interested in submitting evidence of his truthfulness whose scientific reliability appears rather shaky – if and when it is at least above a threshold of mere "junk science."[16] There is no doubt that at present the results of research in fMRI lie detection are already way above this threshold (even if, as yet, they have been derived almost entirely from basic research in laboratories and scarcely been applied to real-life situations). Thus, it can be fully appropriate for a defendant to proffer methods of expert testimony in favor of his veracity that the prosecution could not sincerely think of to proof the opposite. Such measures may well fit his own aims, while being entirely inept and hence inadmissible for prosecutorial purposes of determining guilt. The weak or contested scientific status of such methods of evidence would then be simply a matter of assessing their correspondingly weak probative value, but not a matter of their (in)admissibility.[17]

As to the polygraph, however, criminal courts in the United States as well as in Europe have tended to decide differently.[18] And with regard to the admissibility of fMRI, courts at least in the United States seem to more or less consistently stick to the principles of their reluctant judicature on polygraphy. That is to say, they appear to apply rather uniform standards of scientific reliability to expert testimony regardless of whether that evidence is obtained and assessed for purposes of convicting or of exonerating the accused. Hence, courts seem to ignore the fundamental difference in probative aims and burdens associated with prosecutorial purposes (and duties), on the one hand, and defense goals, on the other.[19]

Dangerous "Seductive Allures"?

Why this is so is not entirely clear. In its landmark decision *Daubert v. Merrell Dow Pharms, Inc.* (1993), the US Supreme Court recognizes that "scientific validity for one purpose is not necessarily scientific validity for other, unrelated purposes" (1993, at 591). This pertains to possible varieties of diverse *scientific* topics whose proof might be the aim of expert testimonies. But why not also apply this

[16]A criterion derived, e.g., from the US Federal Rule of Evidence 702; see *Best v. Lowe's Home Centers, Inc.*, (2009), at 176; a comparable threshold in Art. 244 para. 3 of the German Criminal Procedures Act ("entirely unfit and useless"). However, in accordance with the asymmetry principle in the evidence pointed out in the previous paragraph, the threshold of what counts as "junk science" also varies with regard to what evidentiary goal is at stake: either conviction (prosecutorial) or exonerating (defense-related) purposes of the evidence at hand.

[17]Of course, expert testimony introduced for either prosecutorial or defense purposes may ex post turn out to back up just the opposite purpose, respectively. Then, it must be taken by its probative value for what it objectively supports. Evidently, however, the question of admissibility must be decided ex ante: by assessing the probative value of the evidence for the aim it is intended to further by the party who proffers it.

[18]For the United States see Schauer 2010, p. 1196, n. 23; for Germany and, in passing, a few other European countries see Putzke et al. 2009.

[19]As to the jurisdiction in the United States, cf. the critical voices in the literature cited above; as to Germany, see, for instance, BGHSt 44, 308 (1998).

uncontested rule to the diverse *evidentiary* aims that the parties of a trial pursue? In both these situations, what is at stake are divergent goals which are supposed to be supported by the evidence proffered respectively. If it is true that "the same evidence may be extremely probative for one purpose and not even relevant for another,"[20] why not also concede that it may well be of a (albeit small) probative value for the purposes of one party and not even relevant for those of another?[21] Granted that the state of the art in fMRI for lie detection is "not anywhere near meeting the *Daubert* standard" (Seaman 2009, p. 933). It does not follow, however, that its use in court, if exacted by the appropriate party for their particular goals, is excluded. This not only accords with our considered judgments but also is corroborated by our clear intuitions. Consider the infamous decision of an Indian court that sentenced a woman to life imprisonment for murder in 2008. The verdict was crucially based on evidence from BEOS (brain electrical oscillations signature), a form of EEG brain scanning. It rightly strikes most researchers as well as most legal scholars as outrageous (cf. Giridharadas 2008; Aggarwal 2009). Now, by contrast, consider an acquittal of a suspect based on neuroimaging, for instance, the (hypothetical) ex post acquittal of the woman who, in a recent UK case, was convicted of poisoning a child in her care.[22] She served a prison term of several years but continued to assert her innocence. After her discharge, she was examined in a series of fMRI scans while being confronted with her own and, on the other hand, with the public prosecutor's version of the indicted incident. The results were markedly consistent with her own story. Thus, the scans, while certainly not "proving" that she was innocent, notably demonstrated that she may have been (cf. Spence et al. 2008). Few would find it scandalous had the case been retried on this new evidentiary basis and had the defendant then been acquitted on the "benefit of the doubt" principle.

Still, the postulate of differentiating the applicable standards of validity with regard to who demands an fMRI for what purpose in the trial does not meet with much approval by courts and many scholars. The reason for this seems to be something that is captured, for instance, in the US Federal Rule of Evidence 403. It permits courts "to exclude even relevant evidence if its probative value is substantially outweighed by a danger of confusing the issues or misleading the jury" (cf. US v. Semrau 2012, p. 17). Such a confusing and misleading potential is seen in the frequently invoked "seductive allure" that neuroimaging is believed to unfold vis-à-vis laypersons such as jurors in criminal trials (Weisberg et al. 2008). It has been termed "Christmas tree phenomenon" (Mobbs et al. 2007), alluding to the glittering colors of the computer-generated fMRI pictures indicating the differential blood flow in the examined brain areas. The idea seems to be that jurors or even judges might somehow be overwhelmed by such suggestive effects in their

[20]Brown and Murphy (2010, p. 1155), endorsing the cited evidentiary rule in *Daubert*.

[21]Cf. Merkel (2011, 244 pp.), see also the excellent exposition in Schauer (2010).

[22]The case was not retried, so there has not been an actual ex post acquittal of the convict, but it is not at all far-fetched that there could have been one.

ability to soberly assess fMRI evidence; hence, the admission of fMRI evidence would fly in the face of the Federal Rule of Evidence 403 (Sinnott-Armstrong et al. 2008).

Such concerns have an initial plausibility.[23] On second thoughts, however, they appear rather puzzling. If fMRI can provide relevant evidence for defense purposes, its admissibility is prima facie backed by a fundamental, in some jurisdictions constitutional, right of the defendant. This is obviously a matter of profound legal importance. If, on the other hand, there is a risk of seductive "Christmas tree" phenomena beclouding jurors' and even judges' capacities to soberly assess what's presented to them, why not then instruct jurors and judges how to avoid that risk and interpret the images properly (Feigenson 2006)? That is, why not explain the usually very limited probative value of such evidence even for the modest purposes of the defendant? Why preclude the entire option and thus run the risk of curtailing a defendant's basic rights?

One may suspect that another, rather clandestine intuition is at work here: one of fairness, stipulating a principle of "equality of weapons" between parties to a criminal trial. If the prosecution, so the idea might go, has no chance to introduce fMRI for purposes of conviction, then defendants should not be allowed either to avail themselves of such an opportunity for the opposite aim. But this again seems to rest on a misunderstanding of the roles of the parties in a criminal trial and the asymmetric tasks associated with these roles. From the perspective of the state and thus the public prosecutor, a criminal trial has (or, in any case, should have) nothing to do with a kind of adversarial contest which the prosecution should be determined to "win" by getting the accused sentenced and which therefore should be played on equal terms and premises.[24] Rather, a criminal trial is a procedure to publicly defend the validity of a broken social norm by making the person who is responsible for the breach "pay" for what they did, in order to symbolically reinstall ("repair") the norm's violated normative claim to universal obedience. Against this backdrop, the above-sketched asymmetry in evidentiary requirements between prosecutors and defendants gains its meaning as an imperative of justice, designed to protect notably the innocent, but also the culprit, in their legitimate interest to defend themselves on grounds of the principle *in dubio pro reo*. Hence, it should not be blurred by assimilating the standards of scientific validity required from both parties for the evidence they proffer, respectively.

[23] Notwithstanding their somewhat condescending attitude toward cognitive capacities of jurors, let alone judges, with regard to certain scientific niceties that all of the critics seem to understand without difficulty

[24] Notwithstanding the fact that most common law legal systems incorporate cross-examinations to utilize the dynamics of an adversarial interaction between prosecution and counsel in order to scrutinize the evidentiary material. This adversarial aspect has a purely auxiliary (instrumental) sense; it is not an expression of the genuine character of the trial – not more so, at any rate, than former (now fortunately discharged) methods of ascertaining matters of fact, such as torture. Its purpose is to effectively serve the primary goals of the trial as indicated above. It is not itself one of these goals but a method to achieve them.

Summing all this up, from the perspective of the prosecution and for the aim of conviction, expert testimony based on fMRI lie detection is useless and thus inadmissible. From the perspective of the defense counsel, however, the very same method of evidence may well be suitable and admissible. “Slight support (or weak evidence),” as Schauer puts it, “ought not to be good enough for scientists, but it is often sufficient for the law” (Schauer 2010, p. 1208). And here all the more so, since informal, clandestine, unprofessional, unreliable, and uncontrollable methods of assessing a defendant’s or a witness’ credibility in their testimony are common practice and entirely unavoidable in criminal trials. They include judgments on factors such as “whether a witness looks up or down, fidgets, speaks slowly or quickly, and speaks with apparent confidence” (Schauer 2010, p. 1213), or whether their voices vibrate, they slightly blush or pale, their foreheads show traces of perspiration or their eyelids flicker, etc. The intuitive and entirely unchecked ways of laypersons to interpret such signs as evidentiary clues of veracity or mendacity are certainly much farther off any objective standard of scientific validity than results of fMRI on lie detection. Yet no one could seriously consider their flat-out ban from courtrooms. In short, the admissibility of new methods of evidence on grounds of reliability cannot be assessed entirely independent of what has been admissible from time immemorial.

So the following prognosis appears plausible: Considering the present dynamics of fMRI research on lie detection, its methods will not, and should not, be banned entirely from courtrooms simply for reasons of their alleged infeasibility. Rather, they should be cautiously admitted on a case-by-case basis if proffered by defendants. This proposal, however, stands in need of a range of restrictions and controls, one of them personal, the others factual in character. They elucidate what “cautiously” in the foregoing remark means and requires. I will list them in the following subchapter. Note that we are still concerned here with questions of suitability and admissibility, not yet with problems of a normative in-principle justification of (or objections to) such methods.

Restrictions and Caveats: Personal and Factual

Here’s the personal constraint. As yet, fMRI lie detection appears acceptable only on individuals that have freely consented to its use. None of the known fMRI procedures works to any satisfactory degree if applied against the will of subjects. If they oppose the procedure, they can disrupt its effects by covert countermeasures, i.e., behaviors deployed in order to defy deception detection. Possible countermeasures include physical means, such as biting one’s tongue, or (primarily) mental strategies, such as recalling dramatic and arousing events in one’s life or intensely deflecting one’s attention onto other themes (cf. Ganis et al. 2011; Rosenfeld et al. 2004, on so-called P300-based imagings). With regard to defendants, this simply adds another argument to the one above against an application destined to obtain evidence for their conviction. And as to witnesses, as long as they can avail themselves of such simple ways of making the procedure entirely unreliable,

forced-on fMRI is an inadmissible evidence merely for this reason alone, apart from questions of the legitimacy of such force. However, new methods may arise in the foreseeable future that, with a sufficient degree of reliability, foreclose or restrict subjects' ability to even form mendacious thoughts (see Luber et al. 2009). Such methods would perhaps be apt to even forcibly obtain truthful information from witnesses and would, of course, at the same time pose serious problems of justifiability.[25] At present, however, their practical suitability for the purported aim must be denied.

Now let us take a look at the most obvious and most important factual *caveats*. Some of them have already been touched upon in the arguments of the fMRI skeptics quoted above.

1. Laypeople might, as critics fear, confuse fMRI pictures with something like direct snapshots of the brain during its engagement in cognitive tasks. This is false in various respects, as our above sketch of the scientific principles of fMRI already indicates. Such imagings are computer generated out of thousands of recordings of radio pulses, thus averaging their results over large numbers of single "resonances" of hydrogen protons during extended periods of time and over a range of broadly varying resonant signals. They do not directly show any neural activity (let alone at anyone point in time) but rather make it deducible in a twofold indirect manner: from radio echoes which in turn point to biomarkers that are not part of neural tissue proper but primarily reflect changes in metabolic processes in blood vessels. From these biomarkers, some more steps on the rather extended inferential route from fMRI scans to their courtroom applications still need to be taken. All of these steps require highly skilled professionals in the context of highly sophisticated experimental settings in order to lead to useful insights.
2. Furthermore, up to now by far the most fMRI data obtained in experiments and indicating the presence of either (relatively) normal or abnormal neural processes have their origins in the brains of numerous people, i.e., have been derived from, and averaged over, more or less large numbers of individual subjects in each experiment. This is also true for scans that show brains of people during lying as opposed to others speaking truthfully. The method is designed to "cross out" individual differences that appear on a rather broad scale of variations *within* groups of normal (in our case, truthful) or abnormal (deceptive) people as well as between such groups (Hariri 2009). This makes it difficult, if not impossible, to say with reasonable certitude of any one individual brain scan, which differs in some respects from (loosely speaking) the average "truthful" brain and resembles in just these respects the average "lying" brain, that it actually belongs to the latter group – and thus assures that its owner lied (Faigman 2010; Jones and Shen 2012, p. 356).[26]

[25]Hence, we will briefly return to this topic when discussing in-principle objections to fMRI for lie detection in court (see infra, section "Neuroimaging of Deception (2): Principled Normative Objections?").

[26]To avoid misunderstandings, brains do not lie; people do. The above wording serves as a shortcut only.

3. However, this difficulty of subsuming the results of an individual fMRI scan under a certain type of brain function, and hence of classifying the individual person as belonging to a certain group whose members (say, liars) show, on average, just that type of function, is not the only "translational" problem posed by fMRI. Two more are fairly obvious. One pertains to the highly stylized artificiality of the usually primitive lying tests in the scanner that are actually far off any halfway complex situation of deception in everyday life. And the other, related but more profound, pertains to the fact that people in the test situation are *requested* to lie by the researcher. Hence, their "lies" – if one wants to call such linguistic deviations from what's objectively correct "lies"[27] – are entirely free of stress for those who produce them and, hence, psychologically speaking, do not seem to bear much resemblance to the typical real-world lies (cf. Greely and Illes 2007, pp. 403–404; Editorial Nature Neuroscience 2008). What then do the results of such fMRI "lie test" studies indicate with regard to real-life situations in which the falsehood of a testimony, be it given mendaciously or negligently, may have grave consequences for the life of the individual who utters it? As of yet, no one really knows.
4. When people lie, numerous cortical areas, distributed widely over the whole brain, are involved. Typically, each of these areas is also involved in quite a few other mental activities, possibly very different in character than deceiving. There is no such thing as a "lying area" in the brain.
5. Even the conceptual contours of what is being searched for when a lie-detecting fMRI is applied are not clear. What exactly does "lying" imply? Saying "no" where "yes" would be appropriate? Just telling a somewhat different story from the true one? Omitting something? Concealing, slanting, shading, bending some of what is said? And a fortiori unknown is what kinds of differences in neural activity might correspond to such variations.[28] This difficulty may be overcome to a substantial degree, however, by employing (if suitable for the case in question) "concealed information tests" that do not require any verbal answer on the part of the subject, but only an automatic ("autonomic") response to certain visual stimuli on the part of his brain.

This is a formidable list of possible objections to the use of fMRI for lie detection in criminal trials. However, as we saw above, concerns about validity and reliability of the method can be overcome by first making the requisite distinctions and then, of course, taking all those possible objections into account. With regard to its scientific suitability only, no outright ban is called for.

[27]Which is denied, e.g., by Kanwisher (2009, p. 12). The conceptual question is not very interesting here (and can be decided either way); what is important, however, are possibly profound psychological differences between "lying" in the experimental setting and lying in an important real-world situation.

[28]One must not overlook, however, that these variations on truth and lying are "an omnipresent feature of modern litigation" (Schauer 2010, p. 1194) and thus must be dealt with in court in any case and can only be dealt with under considerable uncertainty, be it with or without the assistance (or distraction) of fMRI.

Neuroimaging of Deception (2): Principled Normative Objections?

There is, however, a further weighty concern, one from a normative perspective. Let's assume that someday fMRI for lie detection will be capable of ascertaining thoughts even from an uncooperative suspect with a high degree of certainty and hence well beyond any of the doubts about its validity discussed above.[29] Would it then be acceptable as evidence? Or would it violate the basic rights of defendants?

Again, we need to draw at least two distinctions in order to tackle this problem: one is between applications on defendants and on witnesses and the other between a compelled use and one consented to by the person concerned.

Compelled Application on Defendants?

Suspects have no legal obligation to actively contribute anything to their conviction. Consequently, they have a right to silence, which includes that no potentially incriminating testimonial evidence be obtained from them against their will or even by force. This privilege against compelled self-incrimination – in its classical Latin form, *nemo tenetur se ipsum accusare* ("no one is obligated to accuse himself") – is a fundamental principle of the law of criminal proceedings. It is also a positive legal norm in many jurisdictions and established in various international covenants.[30] If it comes to precisely determining its scope and content, however, notorious difficulties and long-standing doctrinal controversies arise.[31] They originate mainly from a potential normative conflict with another principle, an equally uncontested norm of procedural criminal law in most jurisdictions: Whereas a suspect must not be forced to actively testify against himself (*nemo tenetur*), his body in all its biological parts may well be examined against his will (if necessary forcibly) and thus be used as physical evidence against him. Put another way, whereas defendants cannot be compelled to reveal anything that might incriminate them with regard to the crime they are suspected of, every piece of their (inner and outer) body may be

[29]This is not sheer science fiction. It may become feasible in the not too distant future by first employing certain measures of brain stimulation that significantly impede a suspect's ability to engage brain networks involved in conscious deceit and then subsequently submit their brains to an fMRI via CIT, i.e., by scanning them for concealed knowledge or memory; cf. Luber et al. (2009).

[30]In the US Constitution, the principle is protected in the Fifth Amendment. The International Covenant on Civil and Political Rights (1966) expressly warrants it in Art. 14 para. 3 (g). And it is usually derived from Art. 6 para. 2 of the European Convention on Human Rights of 1950 ("presumption of innocence until proven guilty") – not a logical deduction, to be sure, but a plausible normative derivation.

[31]The arguments in these controversies are probably similar in most jurisdictions where the principle is guaranteed; they certainly are, for instance, in the US and the German scholarly debate; of the vast doctrinal literature in both these countries, cf. only Pardo (2008), Fox (2009), Verrel (2001), Eidam (2007) – each with a long list of further sources of reference.

forcibly scrutinized to reveal whatever may indicate their involvement in that crime. Obviously, these two principles may collide with each other time and again. Thus, they pose the problem of how to demarcate their respective normative purviews.

In decades of jurisprudential debate about this problem, a variety of differentiating criteria have been developed by courts and scholars, but none has proven entirely convincing or capable of achieving unanimous consent. In the US judicature (as an example for a common-law jurisdiction), the distinction between what is forbidden by the Fifth Amendment and what is not hinges on whether the compelled incriminating evidence from a suspect is "testimonial" or "physical," the former being unconstitutional whereas the latter doubtlessly legitimate (cf. Schmerber v. California 1966).[32] The respective distinction in the judicature of the German Federal Criminal Court (as exemplary for continental or "civil law" systems) rather turns on whether the suspect is compelled to *actively* contribute incriminating evidence of whatever kind and amount (forbidden) or only forced to *passively* endure bodily examinations of whatever kind or scale (allowed).[33]

Against the backdrop of these judicial criteria – and, in fact, of most other criteria proposed in scholarly discourse – the question whether fMRI scans for lie detection would violate the right to silence (*nemo tenetur*, Fifth Amendment) raises a puzzling problem. Is (forcibly) scrutinizing a suspect's brain in order to detect (via a series of inferences) certain mental entities or processes in their consciousness "physical" or "testimonial" in the sense deployed by US courts? That is, does it amount to nothing more than attaining information about physiological processes in one of their organs (their brain) – which would clearly be allowed and hence legitimate ground for whatever (perhaps incriminatory) conclusion to be drawn from it? Or is it rather akin to making them disclose (via their brains) knowledge, thoughts, and memories from their innermost mental sphere – which would just as clearly be forbidden by the *nemo tenetur* principle, or the Fifth Amendment for that matter? Or from the perspective of the German law, is what is extorted from the suspect an *active* contribution to their potential conviction (namely, cascades of brain activities) – which would be forbidden? Or are they only compelled to passively bear an examination of one of their physical organs (from which observers may then draw their own conclusions) – which would clearly be allowed?

In a sense fMRI for lie detection is simply both, depending on how one looks at it. It promises "distinctly testimonial-like information about a person's mind that is packaged in demonstrably physical-like form" (Fox 2009, p. 792). Epistemologically, such perspectivism, yielding different descriptions for the same object, is entirely unproblematic. Normatively speaking, however, fMRI cannot be both allowed and forbidden at the same time. So we must decide what we take it for.

[32]For a thorough examination of the "testimonial/physical" distinction and convincing critique of its shortcomings (see Fox 2009; see also Pardo 2008).

[33]It goes without saying that such an examination must not significantly threaten the suspect's health. For a largely convincing critique of this "active vs. passive" criterion see Verrel (2001).

This is a genuinely normative problem. It cannot be resolved by comparing phenomenal similarities and dissimilarities between fMRI and paradigm types of testimonial as opposed to physical evidence (or of actively contributing vs. passively bearing on the part of the suspect). Instead, we must clarify what deeper principle a suspect's right to silence is based on and then ask whether or not a compelled fMRI for lie detection would contravene that principle's basic normative sense. Simply, albeit correctly, ascertaining that compelled testimonial evidence (or compelled active self-incrimination) is unlawful in criminal proceedings does not explain why this is and should continue to be so and hence does not help us solve our problem.

We cannot enter here the labyrinth of intricate arguments that have been put forward to cope with this problem.[34] Suffice it to say the following: What decisively matters for the prohibition of forcing suspects to testify (actively and/or "testimonially") against themselves is the fact that such compulsion seizes the authority of control over thoughts, memories, knowledge, and other mental processes – in short, the inventory of one's mind and thus over the core of one's personality.[35] Exerting external control over someone's mind in such a way, be it by compulsive threats or by irresistible physical force, deprives a person of a constitutive element of personhood at large. That is to say, being a person in the full normative sense of the concept does not merely involve having a mental inventory of thoughts, reminiscences, emotions, etc. (all of which certainly constitute the individual "I") but also being in immediate command of the processes that dispose of and deal with such elements of the inner self (to the extent they are at one's willful disposal at all).

This is an evaluative, not a descriptive statement, and thus not accessible to scientific proof or refutation. It does, however, plausibly fit our concept of personhood. And it is also significantly confirmed by the historic background against which it should be judged: the so-called "inquisitional" type of criminal trial which for centuries was characterized by outright barbarous procedures of coercing suspects to confess, viz., by subjecting them to torture. The principle of *nemo tenetur* is designed to ban from criminal trials not only such methods but also the related goal of seizing control over a suspect's mind by gaining compelled access to their thoughts and thus depersonalizing them in a certain way and for a certain purpose. Hence, the innermost control over one's mind is declared legally sacrosanct from unwanted access and use by the state in criminal proceedings.

This provides us with a clear answer to our question: Compulsory fMRI for lie detection in suspects is illegitimate and excluded from criminal trials. For in such cases, the brain would not be searched to ascertain physiological activities, which in themselves are uninteresting for any evidentiary purpose, but to gain access to the corresponding mental processes by displacing the defendant as the subject of

[34]For exemplary scholarly analyses, see sources cited supra, n. 31.

[35]A very similar conception in Fox (2009, 796 pp.); relatedly for the German law Verrel (2001, 246 pp.).

control over these processes and their public proclamation. It is of no significance whether this happens via compulsion or via circumventing the controlling position of the individual altogether, i.e., by usurping their privileged access to their own mental sphere and thus extracting part of its content, as it were done in compulsory fMRI. This differentiation between neural activities and correlated mental processes does not rely on a philosophically flawed strong (or "substance") dualism of a Cartesian provenance, as Fox worries (Fox 2009, 793pp.). All monistic conceptions of the mind-brain relationship also presuppose a certain correlation (not interaction!) between mental states and their neural underpinnings, be it one of possible "reduction" of mind to brain processes, one of different "aspects" of one and the same entity, or any of the other conceptions proposed to grasp this specific correlational setting.[36] In our context, we may safely ignore these contested metaphysical problems, anyway. For our distinction between mental processes and brain activities is a purely normative one. Its adequacy does not depend on any particular philosophical position on the mind-brain problem.

Compelled Application on Witnesses?

Witnesses, of course, do not regularly have a right to refuse testimony (specific exceptions aside), much less a right to lie while giving evidence. Would it be legitimate to subject them to fMRI lie detection against their will? As long as they can evade the goal of the procedure by employing simple and effective countermeasures, its application is useless and thus inadmissible.[37] Scientific progress may, however, develop fMRI methods – perhaps, as the case may be, in conjunction with certain forms of brain stimulation (Luber et al 2009) – which are largely immune to such countermeasures. Then? There is no principled or (depending on the jurisdiction in question) constitutional objection that would decisively rule out such an application per se. However, in liberal states or (in Rawlsian terms) in well-ordered societies, the methods of compulsion must, of course, be restricted. Such states should not resort to physical force in order to coerce witnesses into brain scanners. And with regard to our above conclusion that controlling the access to one's own mind is a constitutive function of personhood, it is decidedly preferable for liberal states to also avoid other (nonphysical) forms of compelling fMRI for lie detection on disinclined witnesses.

[36]With, perhaps, the exception of an "eliminative monism" that attempts to somehow dispose of the mental side of brain processes altogether – not a very attractive philosophical position. It is unpromising to deny that we do subjectively experience mental events such as phenomenal states (of "what it's like"), even if they are nothing but "the other side" of brain processes (which we do not subjectively experience).

[37]As we saw above (II.3, supra), if they consent to the fMRI and want to testify in favor of the defendant's innocence, the procedure is not entirely unfeasible and hence may well be considered admissible.

fMRI for Lie Detection on Freely Consenting Suspects or Witnesses Who Request It?

There are no principled objections against such applications in criminal proceedings. And there is no reason to worry about an undue "functionalization" of persons and hence perhaps a violation of their dignity[38] through an fMRI they consented to. Their dignity begins with their choice. As to questions of admissibility, which are a different matter, we may now refer to our above arguments for a differential solution with respect to the different roles and the respective onus of proof of the parties to a criminal trial (see section "Neuroimaging of Deception: Feasibility? Admissibility?").

Conclusions: fMRI for Lie Detection

With regard to the admissibility and legitimacy of fMRI for lie detection, four conclusions from our foregoing considerations suggest themselves:

1. There should not be an outright ban, not even a present-day moratorium, on fMRI-based veracity tests in criminal trials. For prosecutorial purposes of conviction, however, the method is entirely unsuited and hence inadmissible. Not so, by contrast, for the much more modest goal of exonerating the accused under the principle of *in dubio pro reo* ("benefit of the doubt"). That the probative value of fMRI imaging will approach anything near certitude (comparable to DNA tests) in the foreseeable future is extremely unlikely. On the other hand, it is way above any dubious hyperboles of "junk science." Rather, it is an objective of serious research, and it will, in all likelihood, not stagnate at its current level. That this level should make fMRI for lie detection in forensic settings entirely unfeasible, i.e., even for the purposes of defendants and their counsel, is unconvincing.
2. However, the efficiency of fMRI tests can as yet rather easily be undermined by destructive countermeasures of unwilling subjects. Hence, they are only feasible, and thus admissible, if applied on freely consenting defendants or witnesses.
3. On the part of defendants, this holds also for the basic normative reason of their right to silence (principle of *nemo tenetur*) as protected in various international covenants and in national constitutions such as the Fifth Amendment in the United States. This principle forbids extracting possibly incriminating testimonial knowledge from suspects against their will by circumventing their personal control over their own thoughts and memories. This principle does not apply to witnesses. However, because controlling the access to one's own mind is a constitutive element of personhood, witnesses should not be compelled to undergo fMRI for lie detection either. If, by contrast, suspects or witnesses

[38] As was erroneously done in an early decision of the German Federal Criminal Court with regard to polygraphy that was requested by the defendant; see BGHSt 5, 332 (1954).

consent to, or even require, an fMRI test in order to strengthen their credibility, no principled objection stands in the way of complying with their request.

4. If fMRI results are admitted, it must be pointed out to jurors or judges by qualified experts that the value of fMRI as circumstantial evidence to assess the truthfulness of a testimony is usually low to marginal. This holds even for the modest purpose of exonerating the defendant under the principle *in dubio pro reo*. The reasons for this limited probative value must be elucidated to the triers. In particular, the above-listed caveats (see section "Restrictions and Caveats: Personal and Factual" (1–5)) should be expounded in order to counter whatever "seductive allure" or "Christmas tree" effect fMRI results might potentially exert.

FMRI for "Neuroprediction": Assessing Future Dangerousness

The necessity to make forensic prognoses about the future dangerousness of criminal defendants may occur in (at least) two different contexts: for most common law jurisdictions in the sentencing phase of a trial and furthermore (and in "continental" systems *only*) in procedures of preventive detention, which include the coerced confinement of violent sexual offenders as it is established in the so-called sexual predator statutes in many US jurisdictions (cf. Nadelhoffer et al. 2012, 75pp.). Could fMRI be employed for such risk assessments on potentially dangerous people?

Here is the premise that any sensible answer must reckon with: What is at stake in both these types of forensic predictions is the option for the state to impose sanctions on someone for something they have not done (but are only feared to eventually do in the future). It is clear at once that such a practice is somewhat of a borderline case for any legitimate legal order committed to principles of justice.[39] Against this background, it seems cogent that the state is obliged to utilize and exhaust all available, scientifically acceptable methods to ascertain the prognosis of the future dangerousness of a delinquent, given that such a prognosis is indispensable once the question of dangerousness has seriously arisen in a case. At present, it is based on the expertise of (usually two) psychiatrists, a cognitive basis fraught with uncertainties and all too often error (cf. Ennis and Litwack 1974; Thornberry and Jacoby 1979; Monahan et al. 2001) – or even on nothing but juries' or judges' intuitions, a base that's patently unfit to master a task of such importance (cf. Reidy et al. 2013).

[39]This throws into sharp relief concerns of justice about the established practice in many common law jurisdictions to impose harsher penalties than are matched by the degree of guilt (or viciousness, as it were) realized by someone's crime because the perpetrators are believed to pose a future danger to society. One should not be *punished* for something one has not committed (and hence should also not suffer an *extra* penalty beyond what their crimes alone make them deserve) – though one may certainly be *kept detained* if one is rightly assessed to pose a substantial risk of seriously harming others in the future.

Might fMRI scans provide adjuvant support here? Currently, there are at least two mental (or, for that matter, neural) predispositions to re-offend for which fMRI results might yield a sufficiently validated diagnostic and hence prognostic basis: pedophilia and psychopathy. Rather strong empirical evidence indicates a significantly higher risk of recidivism in perpetrators with one (let alone both) of these two mental conditions.[40] It seems that both these conditions can already be assessed with a sufficient degree of reliability by fMRI (for pedophilia cf. Ponseti et al. 2012; Wiebking et al. 2012; for psychopathy Wahlund and Kristiansson 2009; Anderson and Kiehl 2013). In light of these findings, states are not only entitled, but do indeed have an obligation to include "neuropredictive" methods in the prognostic procedures underlying the imposition of measures of preventive detention. Given that the question of dangerousness cannot be avoided, given furthermore how much is at stake for the person concerned (indefinite confinement for something they haven't done), legal decision makers certainly "need to be equipped with the best possible predictions concerning future dangerousness" (Nadelhoffer et al. 2012, p. 76).

Clear as this is, it still raises a few qualms and calls for a few caveats. Not among these qualms, by the way, are concerns about possible violations of the "*nemo tenetur*" principle (in the United States, the Fifth Amendment). That principle only grants protection against self-incriminating testimony with regard to a crime one is suspected to have committed. It does not, however, preclude any effort to obtain as many clues as possible (by legally approved means, of course) concerning their future dangerousness.[41] Here are three caveats:

1. Obviously, fMRI-based predictions cannot replace the classical psychiatric methods of risk assessment. They can only provide an additional or, as the case may be, complementary source of cognition in order to ascertain the broadest base feasible for predictions of potential risks of criminal recidivism.
2. It must be clearly pointed out what fMRI scans can and what they cannot demonstrate. That someone has pedophilic inclinations does not necessarily mean that they will in fact encroach upon children's sexual integrity. According to recent empirical research, quite a few more men (and even women) than ever commit a pedophilic crime do in fact have such inclinations but are able to restrain themselves vis-à-vis the threat of legal punishment (Wurtele et al. 2013). Thus, knowing that someone is a pedophile does not include foreknowing that they will sexually assault children, even if they have already committed at least one such assault in the past (as is regularly presupposed in cases of preventive detention). The same argument holds, and perhaps even more so, for violent offenders who are diagnosed to be psychopaths.

[40]For pedophiles, (see Wilson et al. 2011; Hanson and Morton-Bourgon 2005); for psychopathic offenders (see Olver and Wong 2006; Rice and Harris 2013); for psychopathic sex offenders (see Porter et al. 2009).

[41]The rather unfortunate fact notwithstanding that many common-law jurisdictions confound grounds for punishing past deeds with grounds for predicting future dangerousness (cf. supra, n. 39).
